Preface

The previous seven editions of *Pediatric Nephrology* have established this text as the reference standard for clinical care and research related to the care of the child with kidney disease. The intervening years since the last edition, as is usual, has witnessed a transformation in kidney-related care catalyzed by novel diagnostics, omics-based discoveries, and innovative medications and devices.

As Editors of this eighth edition of *Pediatric Nephrology*, we have aimed to keep up with these changes as well as the shift from hardcopy text reference to more visual and electronic educational structures. We have taken a hard look at the previous editions of *Pediatric Nephrology* and have made substantial changes to the format, scope, and goals of the textbook. Our objectives are to make *Pediatric Nephrology* more relevant to the academic pediatric nephrologist, whether they be focused on clinical care and/or research across the full spectrum of kidney disease in children. For that reason, we have coalesced many of the clinical and science chapters in a single chapter devoted to the topic at hand as well as integrated the pathology content into each relevant chapter instead of a separated chapter. We reduced the size of the textbook from three to two volumes, to make it more concise and affordable, without sacrificing the comprehensiveness of the content. We also worked with the publisher, Springer, to upgrade the illustrative material significantly. *Pediatric Nephrology* is one of Springer's Reference Series textbooks and therefore has the highest priority in their portfolio. Finally, *Pediatric Nephrology* is endorsed as the authoritative textbook in the field by The International Pediatric Nephrology Association.

Much has also changed over the past 6 years in terms of the leadership of the textbook. Drs. Avner, Harmon, Niaudet, and Yoshikowa stepped down as part of a planned editorial succession. In their stead, Drs. Bagga, Bates, and Shroff joined Drs. Emma and Goldstein to complete the editorial team. The additions of these international leaders in basic science, chronic kidney disease, and education have clearly enhanced the depth and quality of this edition.

Sadly, since the publication of the seventh edition, our community has lost Drs. Avner and Harmon. The Editors are extremely grateful to Dr. Avner for his counsel and advice during the negotiations with Springer, and our desire to take the textbook in a new direction, he was completely supportive of our ideas. Dr. Avner was going to write a preface to this edition as well, but although he did not have the opportunity, his support and impact are seen within these pages.

The last few years have certainly given us all pause and time for reflection. The Editors acknowledge all authors who met deadlines despite the whirlwind of additional stresses placed upon us all by the pandemic. Dr. Shroff dedicates this book to her mentor, Professor Lesley Rees. Lesley's contribution to the fields of CKD, dialysis, and nutrition have changed the way a generation of children were treated. She helped train pediatric nephrologists globally, always emphasizing the importance of clinical expertise, dedication to excellence, and compassion. She will be remembered for her humanity, generosity, and graciousness as much as for her many brilliant academic contributions. Dr. Bates dedicates the book to Dr. Michel Baum, a mentor during fellowship and someone who helped him in his career so many ways beyond the training years. He is a true leader in pediatric nephrology having trained so many physicians. He has also been a role model for scholarship in our specialty and has made many groundbreaking discoveries. Dr. Bates also dedicates this book to his wife, Erin, and two children, Helena and CJ, who endured many changes in address and gave him unconditional love and support. Dr. Bagga dedicates this book to all young patients with chronic kidney diseases and their families, living in under-resourced areas of the world, as they navigate their lives through innumerable challenges. These children have given us the opportunity to learn, serve, and optimize their care. Drs. Emma and Goldstein dedicate this book to the memory of their mentor, Dr. William Harmon, who was inspirational to them in so many ways. Dr. Harmon led by example first, do right by the patient and take care of the paperwork later. Furthermore, he listened to what his fellows wanted to do with their career and created the opportunities for them, instead of forcing a path on them.

We hope at whatever stage your career finds you, the eighth edition of *Pediatric Nephrology* serves your needs to provide the best care for your patients and their families and gives you foundation to improve their care in the future. They deserve nothing less.

Contents

Volume 1

Part I Developmental Physiology and Diseases 1

1 Pre-natal Development of the Kidneys and Urinary Tract 3
Carlton M. Bates, Jacqueline Ho, Sunder Sims-Lucas, and Kimberly Reidy

2 Postnatal Renal Maturation 37
Michel Baum and Melissa Anslow

3 Congenital Anomalies of the Kidneys 79
Paul Goodyer, Indra R. Gupta, Rik Westland, and Ihor Yosypiv

4 Stem Cells and Kidney Regeneration 115
Kenji Osafune, Oren Pleniceanu, and Benjamin Dekel

Part II Renal Physiology and Diagnostic Approaches 143

5 Assessment of Kidney Function in Children, Adolescents, and Young Adults 145
Guido Filler, Maria Ferris, and Jyothsna Gattineni

6 Imaging Kidneys and the Urinary Tract 173
Jonathan Loewen and Larry A. Greenbaum

7 Technical Aspects of Renal Pathology 213
Patrick D. Walker, Jan U. Becker, and Agnes B. Fogo

8 Approach to the Child with Hematuria and/or Proteinuria 235
Hui-Kim Yap and Mohan Shenoy

Part III Glomerular Diseases 253

9 Nephrotic Syndrome: Classification and Evaluation 255
Patrick Niaudet

10 Genetic Basis of Nephrotic Syndrome 261
Rasheed Gbadegesin, Moin Saleem,
Beata S. Lipska-Ziętkiewicz, and Olivia Boyer

11 Congenital Nephrotic Syndrome 285
Hannu Jalanko, Timo Jahnukainen, and Kar Hui Ng

12 Clinical Aspects of Genetic Forms of Nephrotic Syndrome 301
Olivia Boyer, Rasheed Gbadegesin, and Aoife Waters

13 Inherited Diseases of the Glomerular Basement Membrane 327
Rachel Lennon, Jie Ding, and Michelle N. Rheault

14 Steroid-Sensitive Nephrotic Syndrome 351
Kazumoto Iijima, Agnieszka Swiatecka-Urban,
Patrick Niaudet, and Arvind Bagga

15 Nongenetic Forms of Steroid-Resistant Nephrotic Syndrome 387
Markus Josef Kemper, Keisha Gibson, and Aditi Sinha

16 Membranous Nephropathy 411
Pierre Ronco, Marina Vivarelli, Rivka Ayalon, and
Hanna Debiec

Part IV Kidney Involvement in Systemic Diseases 435

17 Immunoglobulin A Nephropathy in Children 437
Norishige Yoshikawa and Rosanna Coppo

18 Henoch Schönlein Purpura Nephropathy 465
Koichi Nakanishi, Licia Peruzzi, Agnes B. Fogo,
Brooke Blazius, and Debbie Gipson

19 Renal Vasculitis 489
Seza Ozen, Diclehan Orhan, and Stephen D. Marks

20 Lupus Nephritis 507
Scott Wenderfer, Sherene Mason, Christine Bernal, and
Clovis Artur Almeida da Silva

21 Autoantibodies and Kidney Diseases 541
Rezan Topaloglu, Tanja Kersnik Levart, Michio Nagata, and
Tadej Avcin

22 Membranoproliferative Glomerulonephritis and C3 Glomerulopathy in Children 563
Christoph Licht, Marina Vivarelli, Magdalena Riedl
Khursigara, Matthew C. Pickering, and Patrick D. Walker

23 Thrombotic Thrombocytopenic Purpura, Atypical Hemolytic Uremic Syndrome, and Spectrum of Thrombotic Microangiopathy 595
Magdalena Riedl Khursigara, Stefanie Benoit, Christopher J. Patriquin, Mathieu Lemaire, and Christoph Licht

24 Infection-Related Hemolytic Uremic Syndrome (HUS) 637
Shoji Kagami, Müller Dominik, Michal Malina, and Akira Ashida

25 Acute Post-Streptococcal Glomerulonephritis 659
Hong Xu and Michael J. G. Somers

26 Infections That Affect the Kidney (Nonviral) 673
Arpana Iyengar and Vera Koch

27 Viral Infections and the Kidney 707
Patricio E. Ray, Asha Moudgil, and Aditi Sinha

28 Sickle Cell Nephropathy in Children 735
Thomas Graf, Connie Piccone, and Katherine MacRae Dell

29 The Kidney in Type I Diabetes 751
M. Loredana Marcovecchio and Nektaria Papadopoulou-Marketou

30 The Kidney in Metabolic Syndrome 761
Stella Stabouli and Mark Mitsnefes

31 Renal Manifestations of Metabolic Disorders in Children 779
Francesco Emma, Matthias R. Baumgartner, Diego Martinelli, and Carlo Dionisi-Vici

32 The Kidney in Methylmalonic Acidaemia 799
Patrick Forny, Stephanie Grünewald, and Matthias Baumgartner

33 The Kidney in Mitochondrial Diseases 807
Fatih Ozaltin, Leonardo Salviati, and Shamima Rahman

34 Fabry Disease 821
Michael Beck

35 Hyperoxaluria 831
Bodo Beck, Pierre Cochat, and Yaacov Frishberg

Part V Renal Tubular Disorders 847

36 Pediatric Fanconi Syndrome 849
Takashi Igarashi, Francesco Emma, and Wesley Hayes

37 Cystinosis 877
Elena Levtchenko, William A. Gahl, and Francesco Emma

38 Renal Tubular Acidosis 903
Detlef Bockenhauer, Sergio Camilo Lopez-Garcia, and Stephen B. Walsh

39 Aminoaciduria and Glycosuria in Children 929
Israel Zelikovic and Aude Servais

40 Renal Hypophosphatemia 957
Dieter Haffner and Agnes Linglart

41 Inherited Disorders of Sodium and Potassium Handling . . . 987
Olivier Devuyst, Maria-Christina Zennaro, Rosa Vargas-Poussou, and Lisa M. Satlin

42 Inherited Disorders of Renal Magnesium Handling 1033
Martin Konrad and Karl Peter Schlingmann

Volume 2

43 Inherited Disorders of Renal Calcium Handling 1047
Karl Peter Schlingmann and Martin Konrad

44 Inherited Disorders of Water Handling 1063
Nine V. A. M. Knoers, Elena Levtchenko, and Daniel G. Bichet

45 Pediatric Tubulointerstitial Nephritis 1087
Daniel Landau, Evgenia Gurevich, Sarah Wente, and Lars Pape

Part VI Omeostasis 1105

46 Sodium and Water Disorders: Evaluation and Management 1107
Michael L. Moritz

47 Potassium Disorders: Evaluation and Management 1123
Marta Suárez-Rivera, Lisa M. Satlin, and Melvin Bonilla-Félix

48 Clinical Use of Diuretics 1145
Paul Goodyer, Marina Mir, and Sam Shemie

Part VII Cystic Kidney Diseases and Related Disorders 1169

49 Autosomal Dominant Polycystic Kidney Disease 1171
Melissa A. Cadnapaphornchai and Djalila Mekahli

50 **Autosomal Recessive Polycystic Kidney Disease** 1197
Max C. Liebau and Lisa M. Guay-Woodford

51 **Renal Involvement in Tuberous Sclerosis Complex** 1213
John J. Bissler and Dinah Batchelor

52 **Nephronophthisis and Related Ciliopathies** 1225
Daniela A. Braun and Friedhelm Hildebrandt

53 **Autosomal Dominant Tubulointerstitial Kidney Disease** . . . 1253
Matthias T. F. Wolf and Gema Ariceta

Part VIII Urinary Tract Disorders **1293**

54 **Urinary Stone Disease and Nephrocalcinosis** 1295
Vidar O. Edvardsson and David J. Sas

55 **Urinary Tract Infections in Children** 1323
Giovanni Montini, John David Spencer, and Ian K. Hewitt

56 **Vesicoureteral Reflux in Children** 1343
Tej K. Mattoo and Indra R. Gupta

57 **Pediatric Obstructive Uropathy** 1369
Bärbel Lange-Sperandio and Norman D. Rosenblum

58 **Bladder Disorders** 1399
Tryggve Nevéus, Carlos R. Estrada, and Paul F. Austin

59 **Enuresis** 1411
Søren Rittig

60 **Pediatric Renal Tumors** 1423
James I. Geller, Katherine Vandenheuval, Ethan Smith,
Meera Kotagal, and Luke Pater

61 **Onconephrology** 1445
Russell Whelan, Benjamin L. Laskin, and
Sangeeta R. Hingorani

Part IX Hypertension **1475**

62 **Pathophysiology and Epidemiology of Hypertension in Children** 1477
Ikuyo Yamaguchi, Midori Awazu, and Yosuke Miyashita

63 **Evaluation and Management of Hypertension in Children** 1511
Nicholas Larkins, Empar Lurbe, and Joseph T. Flynn

64 Renovascular Hypertension in Children: Evaluation and Management 1537
Kjell Tullus and Mieczysław Litwin

Part X Acute Kidney Injury 1553

65 Pathogenesis of Acute Kidney Injury 1555
David P. Basile, Rajasree Sreedharan, Rajit K. Basu, and Scott K. Van Why

66 Evaluation and Management of Acute Kidney Injury in Neonates 1593
Jennifer G. Jetton and Enrico Vidal

67 Evaluation and Management of Acute Kidney Injury in Children 1617
Michael Zappitelli, Stuart L. Goldstein, and Zaccaria Ricci

68 Nephrotoxins 1653
Karyn E. Yonekawa, Erin F. Barreto, and Scott M. Sutherland

Part XI Chronic Kidney Failure 1677

69 Progression of Chronic Kidney Disease and Nephroprotection in Children 1679
Elke Wühl and H. William Schnaper

70 Epidemiology and Management of Chronic Kidney Disease in Children 1701
Elaine Ku and Jérôme Harambat

71 Nutrition, Growth, and Development 1717
Vimal Chadha, Bethany J. Foster, Robert H. Mak, and Bradley A. Warady

72 Chronic Kidney Disease – Mineral and Bone Disorder (CKD-MBD) 1751
Rukshana Shroff, Katherine Wesseling-Perry, and Justine Bacchetta

73 Anemia in Chronic Kidney Disease 1779
Isabella Guzzo and Meredith A. Atkinson

74 Assessment of Volume Status in Chronic Kidney Disease . . . 1795
Fabio Paglialonga and Manish D. Sinha

75 Peritoneal Dialysis 1805
C. P. Schmitt, F. Cano, and Alicia Neu

76 Chronic Hemodialysis in Children 1835
Rukshana Shroff, Daljit Hothi, and Jordan Symons

77 Infant Dialysis 1869
Lesley Rees, Motoshi Hattori, and Dagmara Borzych-Dużałka

78 Adequacy of Dialysis 1883
Enrico Eugenio Verrina and Cherry Mammen

79 Renal Transplantation: Evaluation of Children and Donors 1901
Luca Dello Strologo and Ryszard Grenda

80 Renal Transplantation: Surgical and Perioperative Management 1915
Britta Höcker and Jodi M. Smith

81 Renal Transplantation: Immunosuppression and Managing Allograft Rejection 1927
Burkhard Tönshoff, Minnie Sarwal, Stephen D. Marks, and Asha Moudgil

82 Recurrent Disease After Pediatric Kidney Transplantation 1959
Debora Matossian, Patrick D. Brophy, and Priya Verghese

83 Renal Transplantation: Infectious Complications 1973
Arnaud G. L'Huillier and Vikas R. Dharnidharka

84 Renal Transplantation: Non-infectious Complications and Long-Term Outcome 1989
Christina Nguyen and Jaap Groothoff

85 Ethical Issues in Pediatric Nephrology 2017
Aaron Wightman and Michael Freeman

86 Drug Dosing in Abnormal Kidney Function in Children . . . 2031
Mara Medeiros and Guido Filler

Part XII Addendum 2047

87 Normal Reference Values 2049
F. Cano, M. Gajardo, Q. Shen, Edward Nehus, and B. Dixon

Index 2079

Abstract

The mammalian kidney and lower urinary tract maintains and regulates water balance, acid–base homeostasis, electrolyte equilibrium, and waste excretion. The performance of these activities depends on the development of specific cell types in a precise temporal and spatial pattern. Defects in the process can lead to insufficient numbers of nephrons and/or dysfunctional ureters and/or bladders that fail to propel urine forward leading to secondary renal defects. Over the past several decades, considerable advances have been made in understanding the molecular basis for this developmental program. Defects in this program result in congenital anomalies of the kidney and urinary tract (CAKUT), which are leading causes of chronic kidney disease and renal failure in children. These developmental disorders range from renal malformations, such as renal aplasia (absence of the kidney), dysplasia (failure of normal renal differentiation), and hypoplasia (smaller kidneys), to urinary tract abnormalities such as hydronephrosis, vesicoureteral reflux, and duplicated collecting systems. Moreover, many of the molecules identified in animal models as critical for renal development have been validated as important in human CAKUT. This chapter describes renal embryology and molecular control of kidney and urinary tract development, as a means to understand the developmental origins of human CAKUT.

Introduction

The mammalian kidney functions as a key regulator of water balance, acid-base homeostasis, maintenance of electrolytes, and waste excretion. The performance of these activities depends on development of specific cell types in a precise temporal and spatial pattern, to produce a sufficient number of nephrons. Over the past several decades, considerable advances have been made in understanding the molecular basis for this developmental program. Defects in this program result in congenital anomalies of the kidney and urinary tract, which are the leading causes of chronic kidney disease and renal failure in children. These developmental disorders range from renal malformations, such as renal aplasia (absence of the kidney), dysplasia (failure of normal renal differentiation), and hypoplasia (smaller kidneys), to urinary tract abnormalities such as vesicoureteral reflux and duplicated collecting systems. This chapter describes the embryology of the kidney and urinary tract, as a means to understand the developmental origins of these disorders.

Human kidney development starts in the fifth week of gestation, and new nephrons are formed until approximately 32–34 weeks gestation [1]. Remarkably, nephron endowment is quite variable ranging from 200,000 to 1.8 million nephrons per person [2]. Human kidney growth after 34 weeks gestation occurs due to maturation of existing nephrons. Since the mature mammalian kidney cannot compensate for nephron loss due to renal injury by the *de novo* generation of nephrons, the number of nephrons present at birth is an important determinant of long-term kidney health. This idea is supported by the association of reduced nephron number with hypertension and chronic kidney disease [3, 4]. Equally important to nephron endowment is the structural development of each nephron or nephron patterning.

The formation of kidneys in utero involves different critical developmental processes. Differentiation is the process by which precursor cells or tissues mature into more specialized cells. For example, early renal mesenchymal cells have the potential to differentiate into nephron epithelia or stromal cells. Morphogenesis describes the process whereby cells and tissues acquire three-dimensional patterns. This is particularly important in the kidney, as the three-dimensional relationship between the nephrons, vasculature, and collecting system are critical for normal kidney function. Finally, the regulation of cell number at different stages of development is crucial, involving a balance between proliferation and programmed cell death or apoptosis. All of these processes are tightly regulated spatially and temporally during kidney development.

Genetic, epigenetic, and environmental factors all regulate differentiation, morphogenesis, and cell number within the developing kidney [5–7]. Mutational analyses in animal models have provided significant insights into the genetic control of renal development. Genes critical for kidney development in animal models include transcription factors that act as master regulators of other genes, growth factors that signal to other cells, and adhesion molecules that regulate how cells interact with each other and with the extracellular matrix. Increasingly, analyses of humans with congenital renal malformations (such as renal aplasia or duplex kidneys) have frequently identified gene mutations originally described in animal models [8]. Recent studies have also implicated epigenetic mechanisms (defined as heritable changes in gene activity that are not caused by changes in DNA sequence) in regulating nephron formation. These mechanisms include DNA methylation, chromatin remodeling, and non-coding regulatory RNAs [9, 10]. Finally, environmental influences that interact with genetic and epigenetic factors are also important in determining nephron number and patterning. For example, Vitamin A deficiency leads to decreased nephron number in rodents, and has been implicated in renal size in humans [11, 12].

Studying Kidney and Urinary Tract Development

The methods for studying the molecular and genetic control of kidney development have continued to evolve over the past several decades. Visualization of tissue morphology and expression of individual genes and proteins in the developing kidney have traditionally been performed on tissue sections by general staining (e.g., hematoxylin and eosin), detecting messenger RNA (mRNA) via in situ hybridization, or protein via immunohistochemistry (Fig. 1a–c). Technologies to assay the transcriptome of the developing kidney and/or different kidney tissue compartments in a genome-wide, unbiased fashion have advanced significantly in the last decade to encompass high-throughput RNA sequencing, small RNA sequencing and single-cell RNA sequencing (which enables the measurement and analysis of the transcriptome of individual cells within a tissue). These techniques have informed large public databases that describe the gene expression of the developing kidney, including the GenitoUrinary Molecular Anatomy Project, (www.gudmap.org) and Eurexpress (www.eurexpress.org) [13, 14]. These next-generation sequencing approaches are now widely used to identify DNA mutations in the genome (whole exome and whole genome sequencing), changes in chromatin accessibility (assay for transposase-accessible chromatin using sequencing, ATAC-seq), and protein interactions with chromatin (chromatin immunoprecipitation then DNA sequencing, ChIP-seq). Moreover, with the decreasing cost associated with next-generation sequencing, this technology has moved into clinical practice with whole exome and whole genome sequencing often being used to identify mutations associated with kidney disease in patients [15].

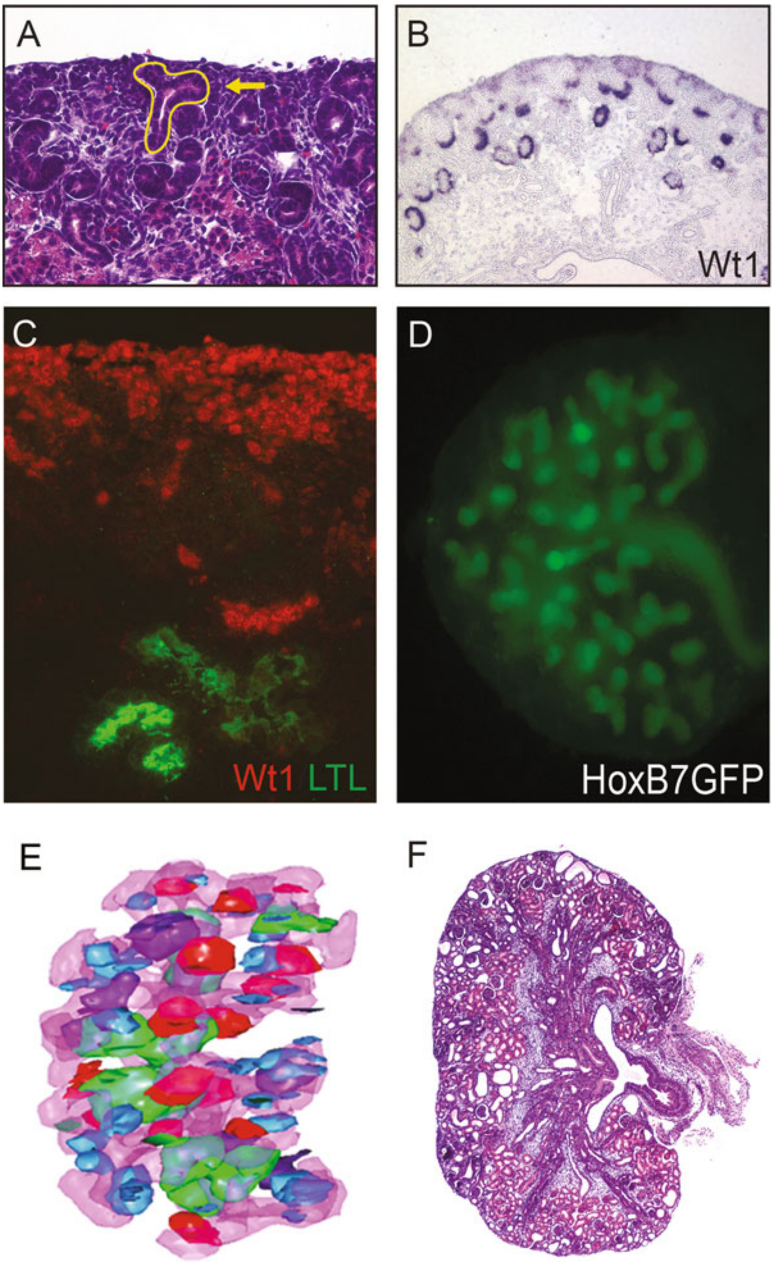

Fig. 1 **Experimental methods utilized to study kidney development**. (**a**) Hematoxylin and eosin (H&E) stained tissue section of a control postnatal day 0 mouse kidney. The ureteric bud is outlined in yellow, arrow points to the cap metanephric mesenchyme. (**b**) In situ hybridization in a control mouse embryonic day 16 tissue section for the transcription factor, Wt1, which stains the metanephric mesenchyme and developing glomeruli. (**d**) Embryonic culture of a transgenic embryonic day 11 HoxB7GFP mouse kidney, demonstrating branching ureteric structures (green) after 5 days of growth. (**e**) 3D reconstruction of an embryonic day 13 mouse kidney with the ureteric epithelium depicted in pink and the developing nephron types including: renal vesicles (blue), comma-shaped bodies (red), S-shaped bodies (purple) and glomeruli (green). (Reproduced with kind permission from Springer Science+Business Media. Sims-Lucas [184], Figure 3F). (**f**) Hematoxylin and eosin stained tissue section of a postnatal day 0 mouse kidney lacking microRNAs in the ureteric lineage using a conditional knockout approach (*HoxB7Cre; Dicer*$^{flx/flx}$)

A classical technique to analyze kidney development is to culture rodent embryonic kidneys *in vitro* as explants. Studies using these methods were the first to show that reciprocal interactions between the metanephric mesenchyme and the ureteric bud are critical to induce the formation of new nephrons and ureteric branching (Fig. 1d) [16]. Moreover, kidney explants allow one to modulate the expression and function of specific genes and proteins using reagents such as antisense oligonucleotides or blocking antibodies. While these experiments have been illuminating, the growth of embryonic kidney explants differs from kidney development *in vivo* in several key ways: lack of blood flow, growth limitations from diffusion of the culture media across the air-media interface, and distortions in the three-dimensional kidney architecture as explants flatten in culture. More recently, efficient and reliable protocols to direct the differentiation of human induced pluripotent stem cells into three dimensional kidney organoids have been developed using insights derived from the study of kidney development [17]. Kidney organoids have emerged as a useful system to study the pathophysiology of diseases like polycystic kidney disease, to understand drug toxicities, and to inform efforts directed towards high-throughput drug screening and renal regeneration. Kidney organoids will be discussed in detail in ▶ Chap. 4, "Stem Cells and Kidney Regeneration."

Because kidney function is critically dependent on the complex three-dimensional structure of the nephron and the number of nephrons that are generated, several methods have been developed to generate more physiological and quantifiable three-dimensional reconstructions of developing kidneys and urinary tracts. One method utilizes serial sectioning through developing kidneys, histological staining, projection of each serial image onto a monitor to identify each tissue lineage, and rendering of the serial images into a three-dimensional image (Fig. 1e) [18]. This technique allows for the quantification of both developing nephron structures and the branching ureteric tree. Optical Projection Tomography can image through the full thickness of a developing kidney that has been whole mount stained for specific cells and permits the quantification of these elements [19]. Advances in imaging techniques (such as novel tissue clearing protocols, light sheet microscopy, and high-resolution confocal microscopy), along with the capability to analyze large image datasets, now provide us with the ability to image fluorescent markers in the developing kidney at higher spatiotemporal resolution in ever-larger, intact samples without phototoxicity [19]. Similarly, advances in magnetic resonance imaging tools offer the potential to count nephron number and analyze local tubular function experimentally, with potential to impact on clinical practice [20].

Physical, chemical, and genetic strategies can be used to manipulate developing kidneys *in vivo*. For example, ureteric obstruction in utero in sheep and monkeys results in hydronephrotic kidneys with renal dysplasia [21, 22]. In addition, dietary manipulations including high doses of vitamin A or dietary protein restriction result in kidney and urinary tract defects [23]. Transgenic approaches have also been used to drive gene expression in specific spatiotemporal patterns, usually in the mouse. In these experiments, a transgenic construct consisting of a tissue-specific promoter and the gene of interest is randomly inserted into genome, leading to expression of that gene in a tissue specific pattern [24]. The limitations of this approach include: (1) that the random insertion can result in unintended changes in gene expression (due to other nearby promoters/enhancers near the site of integration); (2) that the insertion of the transgene into the genome may lead to loss of function of an endogenous gene and; (3) epigenetic factors may silence the construct. The increased utilization of Bacterial artificial chromosome (BAC) constructs, which contain more endogenous promoter elements than are found in traditional plasmid constructs, has led to more faithful and reliable transgene expression.

As opposed to transgenic approaches, homologous recombination is the method whereby a gene is "knocked-out of" or "knocked-into" the mouse genome [24]. Using these methods, a gene of interest is deleted so that it becomes non-functional or an exogenous gene (such as a green fluorescent reporter) is added to the genome at a specific locus. A limitation to traditional knockout techniques are that global loss of function of the gene may result in extra-renal effects (such as early embryonic lethality), which can impact or severely limit the study of the gene's function in the kidney. Given these limitations, it has become more common to perform conditional gene targeting (e.g., with the Cre-/loxP system) (Fig. 1f) and/or inducible gene targeting (e.g., with tamoxifen), allowing for kidney and/or urinary tract specific gene deletion (using a kidney specific Cre-) and/or at a particular time (driving induction of gene targeting with a drug).

While most investigators using genetically modified animals utilize mice, a growing number of scientists study kidney development in other model systems, such as avians, zebrafish, and Xenopus [25]. Advantages of these systems include the ability to produce larger number of embryos in a shorter period of time than in mammals. While many of these models, such as zebrafish and Xenopus usually focus on the pronephros, many of the genes that pattern this "simpler" kidney are required in mammalian metanephric kidneys. Finally, the advent of clustered regularly interspaced short palindromic repeats (CRISPR)/CRISPR-associated proteins (Cas) techniques now allow for relatively quick and easy genetic modifications of virtually any cell or animal model desired [26].

Origin of the Mammalian Kidney

The mesoderm forms as one of the three embryonic germ layers during gastrulation. The mammalian kidney develops from the intermediate mesoderm, lying between the paraxial and lateral plate mesoderm, on the posterior abdominal wall of the developing embryo. In mammals, three pairs of embryonic kidneys develop from the intermediate mesoderm: the pronephros, the mesonephros and the metanephros (Fig. 2) [5, 27]. At the height of their development, the pronephros and mesonephros extend from the cervical to the lumbar levels of the developing embryo. The pronephric and mesonephric nephrons are induced to differentiate by signals from the adjacent nephric ducts, paired epithelial tubules running in a longitudinal course along the embryo on either side of the midline. The nephric duct (also known as the Wolffian duct) continues to grow caudally in the embryos to eventually fuse with the cloaca, which ultimately gives rise to the bladder (see below). The specification of the nephric duct is dependent on the expression of several transcription factors, such as *Paired box 2 (Pax2)*, *Pax8,* and *Gata binding protein 3* (*Gata3*). The pronephros is not functional in mammals, but is the functional kidney in larval fish and frogs. The mesonephros becomes the mature kidney in these lower species and is functional in mammals during embryogenesis. Ultimately, the pronephros and mesonephros largely degenerate in mammals, although remnants of the mesonephros persist in the mammalian male reproductive organs including the rete testis, efferent ducts, epididymis, vas deferens, seminal vesicle, and prostate.

The mature mammalian kidney, the metanephros, is derived from two main tissues, the ureteric bud and metanephric mesenchyme [6, 27]. Starting at approximately embryonic day 10.5 in the mouse and the fifth week of gestation in humans, reciprocal inductive signals cause the ureteric bud to evaginate from the caudal portion of the nephric duct, and the metanephric mesenchyme to condense around the ureteric bud ampulla and tips to form nephron progenitors (Fig. 2). The specification of the metanephric mesenchyme from the posterior intermediate mesoderm requires several transcription factors, including *Odd-skipped related 1* (*Osr1*) [28] and *Lim homeobox 1* (*Lhx1*). The ureteric bud ultimately gives rise to the collecting system, including the collecting ducts, renal calyces, renal pelvis, and ureters [1, 5]. In turn, the nephrogenic metanephric mesenchyme (nephron progenitors derived from the metanephric mesenchyme) differentiates into the epithelial cells that comprise the mature nephron, including the parietal cells and podocytes of the glomerulus, proximal convoluted tubule, the ascending and descending limbs of the loops of Henle, and the distal convoluted tubule [1, 5]. Just after the condensation of the nephrogenic mesenchyme around the initial ureteric bud, a third renal lineage, the stromal metanephric mesenchyme (or renal stroma), appears peripheral to the nephrogenic mesenchyme. The renal stroma

Fig. 2 **Overview of mouse kidney development.** The mammalian kidney originates from the band of intermediate mesoderm sandwiched between the lateral plate and paraxial mesoderm at embryonic day (E) 8.0 in mice. Around E9.0, a population of cells from the anterior intermediate mesoderm (AIM) gives rise to the pronephric duct rostrally and elongates caudally to form the nephric duct (ND). By E10.5 in mice, the ND has migrated close to the cloaca and the rostral and caudal nephric tubules are generated from the AIM and posterior intermediate mesoderm (PIM), respectively. At this stage, the pronephros has undergone apoptosis, the ND gives rise to the ureteric bud (UB) and the metanephric mesenchyme arises from PIM cells present in the nephrogenic cord. At E11.5, the UB, which later elaborates into the entire ureteric collecting duct system, starts dividing with a simple initial 'T-shaped' bifurcation. At this stage, remodeling of the common nephric duct (CND) begins and will ultimately result in the connection of the ureters with the developing urogenital sinus (UGS)/bladder. Around E12.5, metanephric kidney development rapidly progresses, the nephric tubules (MT) are positioned rostrally and connected to the ND, and all components are connected to the UGS through the developing ureter (UR) and the CND. The right-hand panel shows the projection of an optical tomography dataset of CADHERIN-1 expression at E12.0. MES, mesonephros; MET, metanephros. (Reprinted by permission from Springer Nature. Short and Smyth [27], adapted from Figure 1)

develops into perivascular cells, vascular smooth muscle, fibroblasts, mesangial cells, rennin cells, and even some peritubular endothelial cells (see below).

Many key signaling pathways have been shown to drive reciprocal interactions between the ureteric epithelium, the renal mesenchymal lineages, and the renal vasculature [7]. Ureteric bud outgrowth depends on inductive signals from nephron progenitors, stromal cells and angioblasts [6], as well as from itself [29]. The nephrogenic mesenchyme relies in part on signaling from the ureteric bud and renal stroma for self-renewal and well as for initiation of nephron formation [7]. Subsequent nephrogenesis (i.e., patterning and differentiation of nephron epithelia) is highly dependent on factors from both ureteric epithelial and stromal cells.

Nephron Formation

As noted, the metanephric mesenchyme gives rise to nephrogenic mesenchyme or nephron progenitors, which self-renew and have the capacity to form the multiple epithelial cell types of the nephron. Much research has focused this progenitor cell population, which is critical for determining nephron endowment and thus long-term kidney health.

Anatomically, there are several steps that take place in nephron formation [5, 30, 31] (Fig. 3). After the ureteric bud has penetrated the metanephric mesenchyme, nephron progenitors condense around the first ureteric ampulla, forming "cap mesenchyme." As the ureteric bud continues to branch and elongate, the nephrogenic mesenchyme continues to form new caps surrounding each ureteric tip. After the initial few ureteric branches, the earliest cap mesenchymal cells receive spatiotemporal cues to begin the differentiation process to form epithelialized renal vesicles. Subsequent growth and differentiation of the renal vesicle results in formation of the comma-shaped body, which then lengthens to form the S-shaped body. The lower limb of the S-shaped body begins to differentiate into glomerular podocytes. During this time, endothelial cells migrate into the cleft of the lower limb of the S-shaped body and will ultimately form the glomerular capillary loops. Simultaneously, nascent mesangial cells, derived from renal stroma (see below) also migrate into this cleft. Thus, the lower limb of the S-shaped body ultimately forms the glomerulus. Concurrently, the middle and upper limbs of the S-shaped body elongate and differentiate into nephron tubules including proximal tubules, loops of Henle (including descending and ascending limbs) and distal convoluted tubules. The terminal ends of the distal convoluted tubules eventually connect to ureteric epithelia, which ultimately form collecting system (collecting ducts, renal pelvis, and ureters). Nephrogenesis repeats in a radial fashion with

the first nephrons forming in the juxtamedullary regions and last in the peripheral cortex, until the full complement of nephrons is reached.

During prenatal and/or postnatal life, each nephron increases in size and complexity as it matures. Starting in the first month of life, maturing proximal tubules transition from a columnar to cuboidal epithelium, develop microvilli, and increase their tubular dimensions. While the earliest limbs of the Henle loop are located in the renal cortex, subsequent maturation and elongation of these limbs in utero results in the loops pushing through the cortico-medullary boundary in term infants. Postnatal maturation results in the Henle loops eventually reaching the inner renal medulla in the mature kidney. Thus, the urinary concentrating capacity of newborn infants is limited by a reduced medullary tonicity gradient, due to the relatively shorter loops of Henle. Finally, as the distal convoluted tubule matures a portion of the cells are found in close proximity to the future vascular pole of the developing glomerulus, where they develop into the macula densa.

Specification of Nephron Progenitors/Cap Mesenchyme

Differentiation of the intermediate mesoderm and metanephric mesenchyme into nephron progenitors and their derivatives is genetically defined by the sequential upregulation of several transcription factors, cell adhesion molecules, and growth factors [32]. The intermediate mesoderm and early metanephric mesenchyme express the transcription factors *Sal-like 1* (*Sall1*), *Sine oculis homeobox homolog 1* (*Six1*), *Eyes absent homolog 1* (*Eya1*), and the secreted peptide growth factor, *Glial-derived neurotrophic factor* (*Gdnf*). Induction of cap mesenchyme/nephron progenitors by the ureteric bud tips [32–35] is marked by expression of transcription factors such as *Wilms tumor 1* (*Wt1*), *Cbp/p300-interacting transactivator with Glu/Asp-rich carboxy-terminal domain, 1* (*Cited1*) and *Sine oculis homeobox homolog 2* (*Six2*), as well as the transmembrane molecules *cadherin-11* and *α8 integrin*. The earliest epithelial derivative of the cap mesenchyme, the renal vesicle, is marked by the transcription factors *Pax2* and *Lhx1*. In recent years, elegant studies have focused on spatiotemporal expression of these factors in the mouse and human developing kidney comparing the similarities and variabilities between these two species [36]. In addition, high resolution imaging has been used to define the anatomical arrangement of the developing nephrons in mouse compared to humans.

The use of tissue specific gene knockouts generally via conditional transgenic techniques has revealed the importance of several transcription factors (including many mentioned above) in the specification of the cap mesenchyme. Conditional homozygous deletion of *Eya1*, *Six1*, *Pax2*, *Wt1*, *Sall1*, *Six2* or *Lhx1* leads to bilateral renal aplasia or severe renal dysgenesis from defects in cap mesenchyme specification and/or differentiation [36]; these mesenchymal defects are often accompanied by ureteric induction and/or branching abnormalities due in large part due to loss of GDNF signaling from the metanephric mesenchyme. *Pax2* mutant mice generate a metanephric mesenchyme that is unable to differentiate into nephrons and fail to form the nephric duct, which is required for ureteric bud induction. In *Lhx1* and *Sall1* mutants, the metanephric mesenchyme does induce ureteric bud formation, but it fails to elongate and branch and the mesenchyme is once again unable to differentiate into nephrons. In *Wt1* mutants, a defective metanephric mesenchyme forms, but rapidly undergoes apoptosis. SIX2, a specific marker of nephron progenitors, is required for maintenance of progenitor cells, but not for nephron differentiation; deletion of *Six2* in mice results in the formation of ectopic nephron tubules and the rapid depletion of nephron progenitor cells. Similarly, the p53-E3 ubiquitin ligase, Murine double minute 2 (MDM2) appears critical for maintenance of nephron progenitor cells [37, 38].

Recent studies have identified factors that govern the delicate balance of self-renewal and differentiation of nephron progenitors, including WNT genes. Studies from the mid-1990s showed that Lithium chloride, a potent inducer of Wnt signaling, was able to drive tubulogenesis in isolated rodent metanephric mesenchyme cultures

[39–41]. More recently WNT9b, secreted from ureteric bud cells, was shown to be required for the differentiation of nephron progenitor cells [42]. Genetic deletion of *Wnt9b* resulted in a failure of nephron progenitors to undergo the mesenchymal to epithelial transition that is required to form the renal vesicle. A subsequent study revealed that *Wnt9b*, in concert with signals from the renal stroma, plays an essential role in mediating the decision of nephron progenitors to self-renew or differentiate.

Another major signaling pathway that has been shown to mediate nephron progenitors survival is the Fibroblast growth factor (FGF) signaling pathway [42]. FGF ligands are secreted peptides that bind and signal through their receptor tyrosine kinases, FGF receptors (FGFRs). Isolated nephrogenic zone cell culture studies revealed that addition of FGF1, 2, 9, and 20 ligands drive expression of nephron progenitor markers and progenitor proliferation. Furthermore, *in vivo* mouse studies showed that *Fgf9* and *Fgf20* are critical for maintaining nephron progenitor survival, proliferation, and competence to respond to inductive signals. FGF20 mutations in humans were also shown to be associated with severe renal dysplasia. Other work in mice has identified that the FGFRs critical for metanephric mesenchyme development are *Fgfr1* and *Fgfr2*. Combined conditional deletion of *Fgfr1* and *Fgfr2* in the metanephric mesenchyme leads to severe renal dysgenesis.

Several studies have shown that a balance between cell survival and apoptosis is necessary for normal nephron progenitor function. Classic *in vitro* studies using isolated metanephric mesenchyme have shown that nephron progenitors undergo significant apoptosis when cultured without an inducer [43]. Co-culture with isolated ureteric buds or heterologous inducers, such as embryonic spinal cords, dampens apoptosis and drives progenitor survival [5, 44]. Other studies have identified several factors that when added to metanephric mesenchyme or nephrogenic zone cell cultures drive progenitor survival, including Transforming growth factor-β2 (TGF-β2), TGFα, Leukemia inhibitory factor (LIF), Epidermal growth factor (EGF), FGF2, and Bone morphogenetic protein 7 (BMP7) [45–48]. Whether some or all of these factors act as endogenous nephron progenitor inducers remains to be determined. Counterbalancing cell survival, apoptosis is required for normal nephron progenitor function. Moreover, suppression of apoptosis via pharmaceutical or genetic means leads to kidney malformations including abnormal ureteric branching and defective nephrogenesis [49, 50]. Relative "over-abundance" of nephron progenitors also leads to renal epithelial and/or stromal cell defects [51, 52].

Much focus over the last decade has been on understanding what drives nephron progenitors to self-renew versus differentiate. One group found that FGF9 and a potent WNT agonist (CHIR 99021) drove isolated nephron progenitors to renew (instead of differentiating) [33, 53] (see ▶ Chap. 4, "Stem Cells and Kidney Regeneration" for a more in depth discussion of this subject). Another seminal study found that the relative age of a nephron progenitor highly influenced decisions to renew or differentiate [54]. Transplantation of "young" and "old" nephron progenitors into young nephron niche revealed that the older progenitors spent far less time in the undifferentiated state. Thus, it appeared that older progenitors had been imprinted and were more committed to differentiation than the younger progenitors. Other studies have focused on the role of metabolism in governing nephron progenitor decisions to renew or differentiate. One found that p53 (a tumor suppressor) stimulated glycolysis in nephron progenitors, which drove proliferation and self-renewal. Moreover, forcing a switch to aerobic oxidative phosphorylation was sufficient to drive nephron progenitor differentiation [55]. Another study showed nephron progenitor renewal also depended on a relative physiological hypoxia that drives glycolysis and renewal. Moreover, prolonging/exacerbating hypoxia (by lowering oxygen tension or by genetically driving hypoxia inducible factors) forced persistent glycolysis and decreased ability of nephron progenitors to differentiate, all of which could be rescued by using a glycolytic inhibitor [56, 57].

Epigenetic factors also regulate nephron progenitor specification, survival, and potential for differentiation. Histone deacetylases (HDACs) are enzymes that remove acetyl groups from histones, which then modulate (usually stimulate) gene transcription. Class I HDACs are highly expressed in nephron progenitors and are required for proper expression of several key developmental genes including *Osr1*, *Eya1*, *Pax2*, *Wt1*, and *Wnt9b* (among others) [58]. MicroRNAs (miRNAs) are small non-coding RNAs that bind to specific mRNA targets to block translation and promote mRNA degradation. Conditional targeting of *Dicer*, an enzyme required for processing of all miRNAs, in mouse nephron progenitors, led to a loss of the progenitors due to excessive apoptosis, likely from upregulation of the pro-apoptotic protein, BIM. Another study revealed that conditional deletion of a specific miRNA cluster, the miR-17 ~ 92 complex, in nephron progenitors led to a decreases in progenitor proliferation, fewer numbers of nephrons, proteinuria, and podocyte damage. Moreover, these reports was the first to identify a specific miRNA cluster essential for kidney development [59, 60].

Nephron Induction

The initial differentiation step of nephron progenitors is to undergo a mesenchymal to epithelial transition to form the renal vesicle. *In vitro* experiments utilizing isolated rodent metanephric mesenchymal rudiments (similar to and including some of the survival studies noted above) have identified exogenous factors that stimulate nephron progenitors to undergo tubulo-epithelial differentiation [44]. Some of these growth factors can act alone or in concert with others and include FGF2, LIF, TGFβ2, growth/differentiation factor-11 (GDF-11), and WNT1/4. Sequestration of WNT ligands in intact rodent kidney explants by addition of secreted Frizzled-related proteins (sFRPs) led to decreases in mesenchyme-derived tubulogenesis [61]. Mouse genetic experiments have identified at least some of the critical endogenous pathways and growth factors necessary for induction of the mesenchymal to epithelial transition. For example, global deletion of *Wnt4*, normally expressed in renal vesicles, did not perturb cap mesenchyme formation; however, the mutant nephron progenitors were completely unable to form renal vesicles [62]. Conditional deletion of *Fgf8* in the metanephric mesenchyme leads to a block of nephrogenesis beyond the renal vesicle stage, possibly by interacting with Wnt4 to drive of *Lhx1* expression [63, 64]. Interestingly, global deletion of *Fgfr-like 1*, a membrane bound FGF receptor that lacks an intracellular tyrosine kinase domain, also leads to a block in nephrogenesis similar to *Fgf8* conditional mutants [65].

Nephron Segmentation

Establishment of a proper proximal-distal axis is critical for normal nephron segmentation. Reciprocally, repressive interactions between WT1 and PAX2 at early stages of nephron development appear vital to proximal-distal axis patterning [42, 66–68]. In the S-shaped body, WT1 is localized to the lower limb and inhibits PAX2 expression, which together drives cells toward podocyte fates. Transgenic mice with overexpression-expression of PAX2 throughout the embryo including embryonic nephrons develop glomerular defects and renal cystic dysplasia [69]. In contrast, PAX2 is expressed in the upper limb of the S-shaped body and represses WT1 expression, stimulating these cells to become tubular nephron segments.

Two other transcription factors critical for proximal/distal axis patterning of the nephron include *Lhx1* and *Brain specific homeobox 1* (*Brn1)*, both of which are expressed at the renal vesicle stage. Conditional deletion of *Lhx1* throughout the metanephric mesenchyme blocks nephrogenesis at the renal vesicle stage and also leads to a loss of *Brn1* expression [70]. Conditional targeting of *Brn1* in the metanephric mesenchyme does not block proximal nephrogenesis; however, the loop of Henle fails to form and distal convoluted tubules fail to terminally differentiate [71]. These results suggest that LHX1 acts earlier in nephron patterning than BRN1, which is critical distal nephron patterning.

NOTCH receptor signaling, mediated largely by *Recombining binding protein suppressor of hairless (Rbpsuh),* appears critical for proximal nephron patterning. Use of a NOTCH inhibitor in mouse metanephric kidney explants led to a loss of proximal cell fates, including glomeruli and proximal tubules. *In vivo*, conditional deletion of *Notch2* or *Rbpsuh* in mouse metanephric mesenchyme leads to an absence of proximal tubules and glomerular epithelium. Finally, ectopic NOTCH expression in nephron progenitor cells results in the premature differentiation of the progenitors into proximal nephron epithelia [72, 73].

Glomerulogenesis

The first glomeruli form during the nineth week of human gestation. Glomerular capillaries are supported by the mesangium, and the mature glomerular filtration barrier is composed of podocytes with foot processes linked by foot processes, the glomerular basement membrane, and fenestrated glomerular endothelial cells. As discussed above, the glomerular visceral epithelial cell (the podocyte) and parietal epithelial cell originate from cells at the tip of the S-Shape body (the cells furthest from the ureteric bud) (Fig. 3). Vascular endothelial growth factor (VEGF) drives endothelial cell precursors to invade the vascular cleft of the S-shape body. As discussed in more detail below, both angiogenesis (endothelial cell progenitors in the kidney) and vasculogenesis (invasion of endothelial cell precursors from outside the kidney) likely contribute to these endothelial cell precursors, which form the glomerular capillaries. The location of endothelial cell invasion determines the vascular pole of the developing glomerulus. Platelet derived growth factor (PDGF) and its receptor regulate stromally derived mesangial cell progenitors that eventually form the glomerular mesangium.

Podocytes and endothelial cells both secrete the laminins and collagens that form the glomerular basement membrane (GBM). During embryonic development, the glomerular basement membrane composition changes from laminin-1 to laminin-11 and from $\alpha-1$ and $\alpha-2$ type IV collagen chains to $\alpha-3$, $\alpha-4$, and $\alpha-5$ type IV collagen chains. The normal GBM thickness also varies with age, at about 150 nm at birth, 200 nm at one year of age, and 320–370 nm (adult thickness) by age 11 [74].

Nephron and Podocyte Endowment

Since glomeruli form near the tips of ureteric buds, the extent of ureteric bud branching influences nephron and glomerular number. Glomeruli continue to form until 32–34 weeks gestation in humans, whereas glomerulogenesis persists in mice and rats for several days after birth [1]. In newborn humans, the superficial glomeruli are the most immature and are smaller than the deeper juxtamedullary glomeruli [75]. As discussed in ▶ Chap. 2, "Postnatal Renal Maturation," the deeper glomeruli are the first to filter, and increased blood flow to the superficial glomeruli contributes to the increase in glomerular filtration rate after birth. While no new glomeruli are formed after birth, they continue to grow and mature postnatally, reaching their adult size at approximately three and a half years of age [75].

Two thirds of nephrons are formed in the last trimester, and preterm birth may have unique effects on glomerular development. An autopsy study of preterm neonates found that nephrogenesis continues after birth but ceases prematurely; the authors observed abnormal glomeruli with dilated Bowman's spaces and shrunken tufts, suggesting that *ex utero* development may disrupt glomerular differentiation [76]. In addition to nephron number, podocyte endowment may be altered by preterm birth [77]. Preterm birth is associated with higher rates of CKD in children and adults [78]. Focal segmental glomerulosclerosis has been described in children and adults born preterm, suggesting preterm birth may lead to a podocytopathy. Interestingly, children with FSGS and/or CKD associated with *APOL1* high risk gene variant had a high rate of preterm birth [79].

Podocyte Terminal Differentiation

To become podocytes, S-shape cells undergo a marked shape change from columnar epithelial cells to the octopus like shape of the mature podocyte. This shape change is accompanied by alteration in cell adhesion, with apical cell junctions migrating down the lateral aspect of the cells to reestablish cell-cell junctions at the base, the site of the slit diaphragm. The process is guided by Partitioning defective (Par) polarity proteins, which establish cell domains in many types of epithelia. The complex of PAR3/PAR6/aPKC migrates with cell junction from apical to basolateral aspects of the immature podocyte. PAR3 binds to nephrin, establishing the location of the slit diaphragm. Mice lacking podocyte *Par3*, *Par6,* or *aPKC* fail to form podocyte foot processes [80].

Other transcription factors and epigenetic factors, including microRNAs, have also been shown to be critical for podocyte differentiation. Examples of essential transcription factors include *Wt1, podocyte expressed 1* (*Pod1*), *Lim homeobox 1b (Lmx1b)*, and *Mafb*. Several studies utilizing murine genetic knockout models of *Wt1* have demonstrated its critical roles in mediating podocyte differentiation [81–84]. In humans, *WT1* mutations can lead to diffuse mesangial sclerosis, characterized by podocyte differentiation defects resulting in varied glomerular lesions and proteinuria, and can occur as an isolated disease or in association with Denys-Drash or Frasier Syndromes [85–88]. Deletion of *Pod1,* expressed in stromal cells, leads to non-autonomous podocyte defects at the capillary loop stage in mice [89]. Genetic deletion of *Lmx1b* or *Mafb* leads to podocyte differentiation defects past the capillary loop stage [90, 91]. Furthermore, mutations in the *LMX1b* gene in humans leads to Nail-Patella Syndrome, which is often associated with glomerular basement membrane thickening and proteinuria that can progress to chronic kidney disease [92, 93]. Three separate studies showed the importance of microRNAs in maintaining differentiated podocytes in the mouse. Targeted ablation of *Dicer* in murine podocytes, resulting in a loss of all miRNAs, led to podocyte injury, severe proteinuria, and tubular damage starting two weeks after birth [94–96].

Glomerular Capillary Tuft Development

Several signaling cascades have been implicated in the homing and maturation of the endothelial and mesangial precursors to form the glomerular capillary tuft. Vascular endothelial growth factor (VEGF), which is secreted from the podocytes at the S-shaped body stage, promotes recruitment of endothelial precursors to the vascular cleft [97, 98]. A balance of VEGF and a neural guidance factor Semaphorin3a that opposes VEGF is also required for normal glomerular endothelial number [99]. Angiopoietin-1 and -2, growth factors expressed by podocytes and mesangial cells, respectively, are also critical for normal glomerular capillary development [100]. Mesangial cell recruitment into the cleft is largely mediated by the secretion of platelet-derived growth factor (PDGF)–B by endothelial cells, which binds PDGF receptor-β (PDGFRβ) on the mesangial cell progenitors [101]. Mice that lack either *Pdgfβ* or *Pdgfrβ* fail to form glomerular capillary tufts demonstrating the importance of mesangial cell recruitment [102, 103]. Finally, NOTCH2 and its ligand Jagged1 are critical for glomerular endothelial and mesangial cell development. *Notch2* hypomorphic mice and *Notch2/Jagged1* compound heterozygous mice develop glomerular aneurysms and possess no mesangial cells [104].

At the S-shaped body stage, immature podocytes along the lower limb are highly proliferative and have a columnar shape with apical cell attachments and a single-layer basement membrane [105]. Concurrently, endothelial and mesangial cell progenitors are recruited into the lower cleft of the S-shaped body, which will become the vascular pole [106]. While mesangial cells originate from the renal stroma (see below), the developmental origin of the glomerular endothelium is still unclear. Transplantation of avascular rodent embryonic kidney rudiments under neonatal kidney capsule led to formation of endothelial precursors, or angioblasts originating from the graft metanephric mesenchyme [106–108]. However, engraftment of embryonic rat kidney rudiments onto avian chorioallantoic membrane led to vascular ingrowth of avian vessels into the rat glomeruli [109]. As will be expanded on in the vascular development section below, it is likely that both processes/sources contribute to formation of glomerular capillaries.

As the S-shaped body matures, the lower cleft transforms into a cup shape configuration. At this time the podocytes lose their proliferative ability [110] and differentiate, forming foot processes and slit diaphragms, specialized intracellular junctions critical for proper glomerular filtration [111, 112]. Concurrently, the composition of the glomerular basement membrane changes from laminin-1 to laminin-11, and from α −1 and α −2 type IV collagen chains to α −3, α −4 and α −5 type IV collagen chains [113]. Several mouse knockout mice models have shown how failure in these transitions lead to structural and functional glomerular basement membrane defects [114–116]. At this stage of development, the nascent mesangial cells act as a scaffold for the formation of the glomerular capillary loops and ultimately form the supportive core for the entire glomerulus via the deposition of extracellular matrix [117, 118]. Developing glomerular endothelial cells branch extensively during this time and begin differentiating into fenestrated endothelia [1], as detailed in see vascular section below.

Renal Stroma

The renal stroma, like the nephrogenic mesenchyme, is derived from OSR1-positive intermediate mesoderm and the metanephric mesenchyme [119]. A hallmark of the initial renal stroma is expression of the transcription factor, *Foxd1*, which is seen as early as E11.5 in the mouse. The renal stroma is initially located at the periphery of the kidney and interdigitates between the developing nephron units and ureteric tips. One function of the early renal stroma is as a supportive framework for the developing vessels (described further below), nephron progenitors, and ureteric epithelia. As embryonic kidney development progresses, stromal cells are present in both the peripheral renal cortex and in the medulla surrounding developing collecting ducts. At this time, the cortical stroma expresses *Foxd1*, *Aldehyde dehydrogenase 1 family member A2 (Raldh2), β -Catenin, Retinoic acid receptor α* (*Rarα*), and *Rarβ2*, while the medullary stroma expresses *Fgf7*, *Pod1*, and *Bmp4* [119]. In addition, recent studies have shown heterogeneity of individual renal stromal cells using single cell RNA sequencing. Some of the stromally expressed genes and signaling pathways, such as β-catenin, are critical for stromal patterning. Other genes found in the stroma are critical for nephrogenesis and ureteric branching morphogenesis, as shown in mouse knockout studies. At birth, many of the developmental stromal cells have undergone apoptosis and are replaced by nephron segments such as loops of Henle. Many stromal derivatives do survive giving rise to fibroblasts, lymphocyte-like cells, glomerular mesangial cells, renin-expressing cells, vascular smooth muscle cells, pericytes, erythropoietin producing cells and a subpopulation of peritubular endothelial cells.

As noted, signaling from the renal stroma is critical for ureteric morphogenesis [119]. Three genes/pathways expressed within the stroma, retinoic acid, *Foxd1*, and *Pod1,* modulate ureteric branching by regulating expression of RET, a receptor tyrosine kinase expressed in ureteric tips and required for ureteric development (see below). Vitamin A is converted to its active form, retinoic acid, by the enzyme RALDH2 in the renal stroma. Moreover, blockade of retinoic acid signaling in mice, by deletion of *Raldh2* or by combined deletion of the retinoic acid receptors, *Rarα* and *Rarβ2*, leads to hypoplastic kidneys with a reduction in the number of ureteric branches; the ureteric branching defects are linked to downregulation of *Ret* expression in mutant embryos, which in the case of the retinoic acid receptor mutants can be rescued by forced re-expression of *Ret* in the ureteric tissues. *Foxd1* (expressed in cortical stroma and the renal capsule) or *Pod1* (found in medullary stroma) appear to appropriately restrict RET expression to ureteric tips; genetic deletion of either gene leads to mis-expression of RET throughout the entire ureteric tree and subsequent ureteric branching defects.

Non-autonomous actions of the stroma are also critical for nephron development. Mouse genetic studies show that *Foxd1* and *Pod1* are necessary for normal nephron patterning (in addition to ureteric morphogenesis) [89, 120]. Loss of *Foxd1* in mice leads to premature differentiation of stromal cells, which inhibits BMP7-mediated nephron progenitor differentiation [121]. Two studies showed that complete ablation of renal cortical stroma with diphtheria toxin led to abnormally thickened nephron progenitor caps and a decreased ability of progenitors to differentiate [122, 123]. Mechanistically, it appears that loss of the protocadherin FAT4 (when stroma is ablated) perturbs activity of the transcription factors, YAP and TAZ, which in turn disrupts WNT9b signaling and nephron differentiation [122]. Thus, in addition to providing a "framework" for the rest of the developing kidney, the renal stroma actively signals to other renal lineages and differentiates into cells that populate the mature kidney.

Two other derivatives of the renal stroma are cells that excrete renin and erythropoietin to regulate important biological processes throughout the body. The renin producing cells are found in the juxtaglomerular apparatus and regulate the renin-angiotensin system and have critical roles in mediating renal perfusion and GFR [124]. The erythropoietin producing cells in the kidney have been shown to arise from subsets of cortical stroma and their development and matruation are controlled by hypoxia induced factor signaling [125].

Vascular Development of the Kidney

Recent reviews have explored the origin and roles of the kidney vascular system [126, 127], which has become a hot topic as investigators attempt to vascularize renal organoids derived from induced pluripotent stem cells (see ▶ Chap. 4, "Stem Cells and Kidney Regeneration"). The adult kidney receives approximately 25% of the cardiac output. Furthermore, the adult kidney has a high complex vascular network with different functions and therefore different specialized endothelia depending on location [126]. Specifically, three major types of endothelial cells are present within the kidney, including fenestrated (in glomerular capillaries), fenestrated with diaphragms (in peritubular capillaries and ascending vasa recta) and continuous capillaries (in descending vasa recta) (Fig. 4). Not surprisingly, these various endothelial cell types have heterogeneous expression profiles and often appear to have different developmental origins. In addition to endothelial cells, the vasculature includes highly specialized mural cells adjacent to the endothelia; near the glomerulus. These mural cells include pericytes, renin cells, and fibroblasts, while those cells surrounding the peritubular capillaries consist of interstitial pericytes, fibroblasts and erythropoietin producing cells.

Angiogenesis Versus Vasculogenesis

Blood vessels can form by angiogenesis, in which new vessels sprout from existing vessels, or by vasculogenesis, in which *de novo* vessels form from endothelial progenitors. Extensive linage tracing experiments and transplantation studies have shown that both processes likely occur in renal vascular formation [126–130]. The early renal artery and efferent arterioles appear to be primary sites from which new angiogenic vessels sprout within the developing kidney. Simultaneously, renal endothelial progenitors (marked by *Flk1/Vegfr2*) form primitive vascular networks, particularly within the renal stroma, that subsequently join with and are pruned by the angiogenic vessels. The vasculogenic endothelial cell progenitors within the kidney appear to arise from the *Osr1*-expressing intermediate mesoderm, as is the case with the rest of the metanephric kidney. Finally, specification of the endothelium (whether angiogenic or vasculogenic in origin), including arterial, venous, capillary, or lymphatic fates is driven by growth factor signaling pathways and transcription factors, including VEGF, EPHRIN, NOTCH, and SOX [131].

Origins of the Peritubular Capillary Endothelia

While formation of glomerular capillaries has been extensively studied (see above), the origin of peritubular capillaries has been less well defined. Two studies, however, have found that peritubular capillaries arise from a combination of resident endothelial progenitors as well as invading angiogenic vessels [126, 127]. One intriguing study found that *Foxd1*-positive renal cortical stroma cells give rise to a subset of the peritubular endothelia but not the glomerular endothelia.

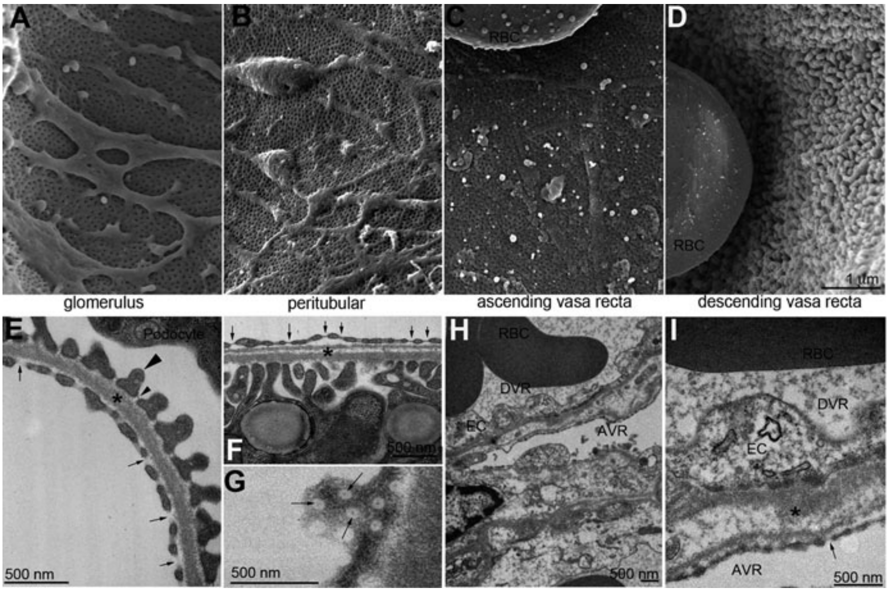

Fig. 4 **Electron microscopy demonstrating the varied renal endothelial cell types.** (**a, e**) Glomerular capillaries contain fenestrated endothelium without diaphragms (E, arrows) and share a basement membrane (*) with podocyte foot processes (large arrowhead) that are separated by slit diaphragms (small arrowhead). (**b, f, g**) Peritubular capillaries have fenestrated endothelial cells that are covered with diaphragms (**f**, **g**, arrows) and have a thick basement membrane (*) separating them from the tubular cells. (**c, h, i**) Ascending vasa recta (AVR) also have fenestrated endothelia with diaphragms (**c**, **h**, **i**, arrow). (**d, h, i**) Descending vasa recta (DVR) possess endothelia that are non fenestrated, but thick and continuous (**d**, **h**, **i**). *RBC* red blood cell, *EC* endothelial cell. Panels A–D= scanning electron micrographs. Panels E–I= transmission electron micrographs. (Reproduced with kind permission from Springer Science+Business Media. Stolz and Sims-Lucas [126], Figure 2)

These stromal cells have the potential to grow into endothelial cells within tumors when co-cultured with cancer cells and loss of these cells leads to kidney patterning defects in mice [132].

Molecular Control of Renal Vascular Development

A key signaling pathway mediating renal vascular development is the VEGF pathway. VEGF ligands are expressed early in the metanephric mesenchyme and later in the developing glomerular podocytes, distal tubules, and collecting ducts and at low levels in the proximal tubules [133, 134]. Developing endothelial cells, including those that arise from existing vessels and those forming *de novo*, express VEGF receptors; thus VEGF signaling appears to drive both angiogenesis and vasculogenesis within the kidney. Interestingly, *Vegfr2* is present on the apical surface of ureteric epithelium, which likely accounts for the stimulatory role of VEGF on ureteric growth (see below).

Hypoxia inducible factors (HIFs), a family of transcriptions factors, are likely master regulators of angiogenesis and vasculogenesis within the developing kidney [57, 135]. These molecules are activated during periods of low oxygenation, as occurs during embryogenesis, and are down regulated postnatally. The HIF genes are largely located in the nephrogenic zone, including podocytes, developing collecting ducts, and developing endothelial cells. HIF proteins induce expression of VEGF ligands, *Vegfr1* and *Vegfr2*, during kidney development by directly binding to hypoxia responsive elements on those genes.

Angiopoietin (ANG) growth factors that bind to TIE receptors also appear to have critical roles in renal vascular development and are at least in part regulated by HIF and VEGF signaling [136]. ANG1, which is expressed in the metanephric mesenchyme, maturing nephron tubules, and podocytes, signals through TIE2, which is expressed on endothelial cells. Conditional deletion of *Ang1* or *Tie2* in mice leads to glomerular capillary defects including endothelial cells that do not attach to the basement membrane. ANG2, expressed in vascular smooth muscle cells and pericytes, binds to TIE1 that is expressed by endothelial cells. Genetic deletion of *Ang2* leads to upregulation of TIE2 signaling and significant defects in renal peritubular capillaries.

Finally, the NOTCH signaling pathway appears to regulate renal angiogenic vessel outgrowth [137]. NOTCH receptors induce sprouting by stimulating expression of *Vegfr2* in vascular tip cells. Simultaneously, NOTCH inhibits VEGFR2 signaling in adjacent vascular stalk cells, causing them to remain dormant. Thus NOTCH regulates the pattern of branching in angiogenic vessels.

Collecting System Development

Ureteric bud formation begins in the fifth week of gestation in humans and at embryonic day 10.5 in mice. As noted previously, signals from the metanephric mesenchyme cause the ureteric bud to form from the nephric duct and then invade into the mesenchyme. Overall, collecting duct system development includes: (1) ureteric bud induction and outgrowth; (2) ureteric branching morphogenesis; and (3) cortical and medullary collecting duct patterning, all of which is discussed in more detail below.

Ureteric Bud Induction and Outgrowth

Failure of ureteric bud outgrowth results in renal aplasia, which can occur unilaterally or bilaterally. The *Glial cell line-derived neurotrophic factor* (GDNF) – *Ret proto-oncogene* (RET) signaling pathway is crucial for bud outgrowth. The receptor tyrosine kinase *Ret* and its co-receptor *Gdnf family receptor alpha 1* (*Gfrα1*) are expressed in the nephric duct, the initial ureteric bud and later in branching ureteric tips, while its ligand, *Gdnf*, is present in the metanephric mesenchyme (Fig. 6) [27]. Targeted deletion of *Gdnf, Ret,* or *Gfrα1* in mice generally results in bilateral renal aplasia due to a lack of ureteric bud outgrowth [27]. Heterozygous mutations of RET have also been identified in humans with bilateral renal aplasia, and a rare RET polymorphism has been reported in individuals with non-syndromic vesicoureteral reflux [138, 139]. The renal aplastic phenotype is not fully penetrant in a subset of *Gdnf*$^{-/-}$ or *Ret*$^{-/-}$ mutant mice [140, 141], suggesting that other molecular pathways also play a role in ureteric bud outgrowth. For example, genetic inactivation of several extracellular matrix (ECM) or ECM-interacting proteins such as members of the *Fras-Frem-Grip1* complex, *Laminin-5*, *Nephronectin* and *α8 integrin* also result in failure of ureteric bud outgrowth [27].

Many studies have focused on the molecular mechanisms that regulate GDNF-RET expression and/or signaling [27]. *In vitro* studies with GDNF-soaked agarose beads show that the entire length of the nephric duct is competent to respond to GDNF by initiating ectopic ureteric bud formation [142, 143]. Moreover, mice that ectopically express *Gdnf* or *Ret in vivo* develop renal malformations such as duplex kidneys and hydronephrosis [144, 145]. Together, these data show that GDNF-RET signaling must be tightly spatially regulated for the ureteric bud to form in the correct location from the nephric duct, ensuring that paired single kidneys form at the appropriate position in the body (Fig. 5).

Several genes are thought to be crucial in restricting *Gdnf* to the posterior intermediate mesoderm including, *Forkhead box c1* (*Foxc1*), *Foxc2*, *Slit guidance ligand 2* (*Slit2*), and *Roundabout Guidance Receptor 2* (*Robo2*) (Fig. 5) [27]. Homozygous mutant mice for these genes develop ectopic ureteric buds, multiple ureters and hydroureter, as a result of ectopic *Gdnf* expression. *Foxc1* and *Foxc2* encode transcription factors that suppress *Gdnf* expression in the metanephric mesenchyme. In the developing kidney, *Slit2* is expressed in the nephric duct, and *Robo2* is detected in the metanephric mesenchyme. Together, the SLIT2-ROBO2 pathway is thought to regulate the bioavailability of *Gdnf*. ROBO2 mis-sense mutations in humans have been identified in families with vesicoureteral reflux and/or duplex kidneys [146].

Fig. 5 Molecular determinants of ureteric bud formation. Ureteric bud outgrowth is dictated by a complex genetic network centered around interactions between Gdnf and its receptors Ret and Gfrα1. This schematic shows some of the principal players in this process, many of which act to suppress inappropriate Gdnf production and/or signaling downstream of Ret along the nephric duct, except at the site of ureteric bud induction. Loss of these controls often results in ectopic ureteric bud formation. Ureteric bud outgrowth at the level of the embryonic hindlimbs is facilitated at around embryonic day (E) 10.5 (E24 in humans) by the concerted actions of several growth and transcription factors that result in the production of Gdnf in the metanephric mesenchyme and the reciprocal activation of Ret signaling. (Short and Smyth [27], adapted from Figure 3)

Two other genes, *Sprouty1* (*Spry1*) and *Bone morphogenetic protein 4* (*Bmp4*), modulate the response of ureteric bud epithelial cells to GDNF-RET signaling (Fig. 5) [147]. Loss of *Spry1*, which is normally expressed in the nephric duct, results in ectopic ureteric bud induction, multiple ureters, multiplex kidneys, and hydroureter [147, 148]. *Spry1* mutant embryonic kidneys have increased expression of *Gdnf* and GDNF-RET target genes, and have increased sensitivity to GDNF-induced ureteric induction in organ culture. Mice heterozygous for *Bmp4* have ectopic or duplicated ureteric buds, resulting in hypo-dysplastic kidneys, hydroureteronephrosis and ureteral duplications. BMP4 mutations have also been described in humans with renal tract malformations [149]. *Bmp4* expression itself is inhibited by *Gremlin 1* (GREM1), and together with aforementioned genes, functions to ensure that only one ureteric bud is induced from the correction position along the nephric duct [147].

The downstream effects of GDNF-RET signaling, namely, ureteric bud proliferation, survival, and ureteric outgrowth and branching are mediated by several transcription factors, including *SRY box transcription factor 8* (*Sox8*), *Sox9*, *Ets variant transcription factor 4* (*Etv4*) and *Etv5*. Combined deletion of *Etv4* and *Etv5* causes bilateral renal aplasia in mice [148]. *Etv4* and *Etv5* drive expression of several critical genes in the ureteric bud tip, including *Wnt family member 11* (*Wnt11*), *C-X-C motif chemokine receptor 4* (*Cxcr4*), *Matrix metallopeptidase 14* (*Mmp14*), *Myb proto-oncogene* (*Myb*) and *Met proto-oncogene Met* [148]. Furthermore, genetic deletion studies in mice have shown that *Wnt11* is necessary for normal *Gdnf* expression in the metanephric mesenchyme [150].

Ureteric Branching Morphogenesis

After growing into the metanephric mesenchyme, the ureteric bud bifurcates into a T-shaped structure. The ureteric bud then continues to branch, ultimately generating about 15 generations of branches, with the earliest branches remodeling to form the calices and renal pelvis [27]. The process of ureteric branching includes: (1) expansion of the ureteric bud at its leading tip (termed the ampulla); (2) division of the ampulla to form new branches; and (3) elongation of newly formed branches (also referred to as the ureteric trunk). In humans, during the first 9 generations of branching, ureteric bud tips induce formation of new nephrons from the surrounding cap mesenchyme at about a 1:1 ratio [1]. Ureteric bud branching is completed by the 20th—22nd week of human gestation, and subsequent collecting duct maturation occurs by elongation of peripheral (cortical) segments and remodeling of central (medullary) segments. At this stage, four to seven new nephrons are induced around each tip of a terminal collecting duct branch [1, 5].

Localized cell proliferation occurs in both the ureteric tip and ureteric trunk compartments; however, time lapse imaging has demonstrated that a subpopulation of ureteric tip progenitors remain in the tip niche to undergo sustained proliferation and drive subsequent branching [27]. Interestingly, ureteric tip cells undergo intraluminal mitosis, an unusual feature for epithelial proliferation. Cell survival is also critical for normal renal branching morphogenesis; defects in cell survival are associated with renal cystic dysplasia and urinary tract dilatation. Moreover, targeted deletion of the apoptosis regulator *Bcl2* [151] and *Transcription factor Ap-2* (*AP-2*) [152], genes critical for cell survival, results in increased apoptosis and collecting duct cysts in mice.

Several signaling pathways are necessary for branching morphogenesis. In addition to its role in ureteric bud induction, GDNF-RET signaling is critical for ureteric branching and appears to mediate dynamic changes in cell migration at the ureteric tip [27, 147]. In chimeric embryos with cells of varying *Ret* activity, the cells that express the highest level of *Ret* move to the ureteric bud tip, closest to where *Gdnf* is expressed by the metanephric mesenchyme. *Wnt11* (expressed in ureteric tips) is necessary for maintaining normal *Gdnf* expression; conversely, *Wnt11* expression is reduced when GDNF signaling is absent. Furthermore*,* *Wnt11* mutant mice have defective ureteric branching morphogenesis, and thus develop renal hypoplasia. Finally, conditional targeting of *β-catenin*, a key mediator of canonical WNT signaling, in the ureteric lineage results in aberrant branching, loss of ureteric bud tip gene expression, and premature expression of differentiated collecting duct genes.

Fibroblast growth factor (FGF) signaling is also critical for ureteric branching. *In vitro* studies have shown that exogenous FGF ligands differentially modulate ureteric bud growth and proliferation [153]. FGF10 preferentially stimulates proliferation at ureteric bud tips, whereas FGF7 increases cell proliferation throughout the developing collecting ducts. *In vivo*, global deletion of *Fgf7* or *Fgf10* in mice results in ureteric branching defects and hypoplastic kidneys. Conditional targeting studies in mice have revealed that fibroblast growth factor receptor 2 (FGFR2) is likely the key FGF receptor mediating effects on ureteric branching [154]. Loss of *Fgfr2* in the ureteric bud results in hypoplastic ureteric ampullae with reduced proliferation and increased apoptosis, ultimately leading to a significant reduction in ureteric branching and hypoplastic kidneys. In addition, another study revealed that while combined loss of *Sprouty1* and *Gdnf* in mice largely rescues ureteric defects compared to when either locus is deleted alone, additional loss of *Fgf10* in the combined mutants led to complete loss of ureteric branching and renal aplasia [148]; thus, FGF signals appear to be able to largely substitute for GDNF in promoting ureteric morphogenesis in the absence of *Sprouty1*. Finally, a combination of *in vitro* and *in vivo* experiments revealed that FGF signaling acts in a coordinated fashion with *Wnt11* and *Gdnf* to regulate ureteric morphogenesis, in concert with *Sprouty* genes [155].

Advances in imaging techniques that permit detailed analysis of the morphometric parameters of intact developing kidneys have allowed researchers to quantify branching morphogenesis *in vivo* [27]. These approaches have provided insights into how well the branching pattern of the developing kidney is conserved, with relative uniformity and increases in branching complexity observed early in kidney development. Recently, factors that regulate the spatial arrangement of different branches in the kidney have also been described. Moreover, branching in the kidney often occurs through asymmetric branching that arise through suppression of bifurcations between growing ureteric tips and that is not impacted by nephron formation [19, 156]. The reaction-diffusion model described by Turing in 1952 proposed a theoretical mechanism to explain how spatial patterns could form from the interaction of two diffusible substances, even from an initial random or uniform condition [157]. Mathematical modeling of embryonic kidney explants has shown that ureteric branching is most compatible with a ligand-receptor based Turing-type model based on GDNF-RET signaling; furthermore, WNT11-driven maintenance of GDNF expression appears important in determining the distance between forming ureteric buds [158].

Cortical and Medullary Collecting Duct Patterning

From the 22nd-34th week of human gestation [1] and embryonic day 15-birth in mice [5], the cortical (peripheral) and medullary (central) regions of the kidney become established. The relatively compact, circumferential renal cortex comprises approximately 70% of the mature kidney volume [159]. The renal medulla develops as a modified cone shape, and occupies the remainder of the mature kidney volume. The apex of the medullary cone consists of collecting ducts converging in the inner medulla, and is termed the papilla. Ultimately, medullary collecting ducts become morphologically distinct from cortical collecting ducts. Medullary collecting ducts become elongated, linear, and remain relatively unbranched in a region devoid of glomeruli. In contrast, collecting ducts in the renal cortex remain branched and during development, induce nephrogenic cap mesenchyme to form nephrons throughout nephrogenesis.

These morphological differences are likely due in part to distinct axes of growth in the developing renal cortex and medulla. The renal cortex grows circumferentially, which preserves the organization of the peripheral tissues, including differentiating glomeruli, nephron tubules, and collecting ducts [159]. In contrast, the developing renal medulla expands longitudinally, perpendicular to the axis of cortical growth, due to elongation of outer medullary collecting ducts. Stromal cells may be a source of stimulatory cues for the medullary growth [159]; studies have shown that mice lacking the stromal transcription factors *Forkhead box D1* (*Foxd1*) and *Transcription factor 21* (*Tcf21*) have abnormal medullary collecting duct patterning [160]. Finally, apoptosis appears to participate in physiological remodeling the branched medullary ureteric tissues into elongated tubules, as programmed cell death normally occurs prominently in the developing medullary ureteric epithelia that become the papilla, calyces, and renal pelvis [51].

Multiple genes have been implicated in the differentiation of cortical and medullary collecting ducts, including those that encode for soluble growth factors (*Fgf7*, *Fgf10*, *Bmp4*, *Bmp5* and *Wnt7b*), proteoglycans (*Glypican 3* (*Gpc3*)), cell cycle regulatory proteins ($p57^{KIP2}$), and components of the renin-angiotensin axis (*Angiotensin* [*Agt*] and *Angiotensin type 1* and *2 receptors* [*Agtr1* and *Agtr2*]). *Fgf7* mutant mice have marked papillary underdevelopment, while *Fgf10* null kidneys exhibit medullary dysplasia with fewer loops of Henle and medullary collecting ducts, increased medullary stroma, and enlargement of the renal calyx [153]. The ability of FGF ligands to bind properly to their receptors require interactions with cell surface proteoglycans, including glypicans. GPC3 is required for normal medullary patterning in humans and mice [153]. Moreover, the medullary dysplasia observed in *Gpc3* deficient mice appears to result from unrestrained proliferation and overgrowth of the ureteric bud and collecting ducts, followed by aberrant apoptosis [161, 162]. The *Gpc3-/-* mouse medullary defects appear to be driven by altered responses of mutant collecting duct cells to growth factors including FGFs [162]. Finally, mice lacking the cell cycle protein $p57^{KIP2}$ demonstrate medullary dysplasia, with fewer inner medullary collecting ducts [163]. Together, these studies reveal the importance of balanced cell proliferation and apoptosis in medullary collecting duct patterning.

Proper elongation and growth of medullary collecting ducts also appears to rely on oriented cell divisions. Studies have shown that canonical WNT signaling in collecting ducts via WNT7b is required for the formation of the renal medulla, and leads to properly oriented cell division and survival [147, 164]. Furthermore, α3β1 integrin and the receptor tyrosine kinase c-MET act in concert to regulate *Wnt7b* expression and signaling in medullary collecting ducts [147].

Finally, angiotensin and angiotensin receptors appear critical for development of the renal calyces, pelvis, and ureter. Mice lacking *Agt* or *Agtr1* genes demonstrate progressive widening of the calyx, and atrophy of the papillae and underlying medulla [160]. These defects appear to be caused by decreased proliferation of the smooth muscle cells that line the renal pelvis. Loss of *Agtr2* causes a range of renal anomalies secondary to ureteric mispatterning, including vesicoureteral reflux, duplex kidneys, renal ectopia, uretero-pelvic or uretero-vesical junction stenoses, renal dysplasia or hypoplasia, multicystic dysplastic kidneys, and renal aplasia [160]. The renin-angiotensin system also appears to regulate ureteric bud branching morphogenesis, papillary collecting duct proliferation and survival, and the expression of multiple genes implicated in renal medulla development [147].

Lower Urinary Tract Development

Anatomic and Functional Development

Concurrent with metanephric kidney development, the embryonic ureter and bladder form, the former functioning to propel urine into the latter, which stores urine until an appropriate time to expel it via the urethra. Similar to the kidney, the ureter and bladder undergo maturation largely due to reciprocal interactions between an epithelium (i.e., urothelium) and surrounding mesenchyme that forms the lamina propria, muscle, and adventitia (Fig. 6). For reviews on anatomic and molecular control of lower urinary tract development, see [165–167].

Ureter development begins simultaneously with metanephric kidney development around the fifth week of gestation in humans and at E10.5 in the mouse, when the ureteric bud arises from the nephric duct [165, 168]. Thus the embryonic origin of the ureteral urothelium is the intermediate mesoderm, the same as the metanephric kidney. By E11.5, the ureteric bud has been segmented into a distal portion that will develop into the ureter and a proximal end that has invaded the metanephric mesenchyme to eventually branch and form the collecting ducts and renal pelvis (see above). The mesenchyme surrounding the early developing ureter consists largely of tailbud-derived mesenchyme that appears to be crucial for directing the distal ureteric bud toward a ureter fate [165]. Between E10.5 and 13.5, the nascent ureter transitions from attaching to the nephric duct to emptying directly into the early bladder (see below). By E13.5, a thin outer ring of ureteral mesenchyme condenses and expresses alpha smooth muscle actin (αSMA) mRNA, the first marker of differentiation toward a smooth muscle fate [169]. Expression of αSMA protein is not noted until E14.5 in the proximal portion of the ureter (nearest the kidney) and then throughout the entire length of ureter by E16.5; thus, ureter muscle development progresses in a rostral to caudal direction [165]. Concurrent with mesenchymal development, the ureteral urothelium gradually matures from a simple epithelium to a stratified epithelium consisting of at least three cell types with distinct structural features and molecular markers: Basal, Intermediate, and Superficial/Umbrella cells (Fig. 7) [166]. The cell layer that houses embryonic ureter urothelial progenitors is not entirely clear. One mouse study suggests that urothelial Basal cells, arising from the original ureteric epithelium, serve as the progenitors for other ureteral urothelial cell types [165]. A more recent mouse lineage tracing study suggests that both Superficial and Basal cells arise from an Intermediate cell progenitor [166]. A unique feature of mature urothelium (compared with other epithelia) is that Superficial cell and subsets of Intermediate cells express urothelial plaques, consisting of uroplakin (UPK)

proteins (Fig. 7), which provide a permeability barrier and act as a binding site for uropathogenic E. coli (among other functions) [166].

An important function of the ureter is to continuously propel urine from the renal pelvis to the bladder. The ability of the ureter to undergo peristaltic waves of contraction followed by relaxation appears to be intrinsic and not dependent on urine flow; cultured explants of E13.5 mouse ureters attached to kidneys begin to undergo spontaneous peristaltic contractions within a few days, as do isolated and cultured E15.5 ureters [165]. Elegant studies identified a population of modified smooth muscle cells that act as pacemakers at the junction of the renal pelvis and the kidney and that express hyperpolarization-activated cation–3 (HCN3) channels (a family of channels that are also present in cardiac pacemakers) [165]. Loss of HCN3 activity in mice leads to abnormal coordination and frequency of ureter contractions [165]. Following this study, another described a population of secondary pacemakers that are located in the muscle of the mouse proximal ureter (starting at the ureteropelvic junction), and that have morphological and molecular features similar to intestinal pacemakers including expression of *c-Kit* [165]. As with *Hcn3*, knockdown of *c-Kit* expression led to cessation of ureteral peristalsis [165]. Thus, like the cardiac conduction system, the ureter has primary and secondary pacemakers that act to drive urinary propulsion in a coordinated fashion.

The embryonic bladder initially forms around the fifth gestational week in humans and at E11.5–12.5 in the mouse [167, 168]. Unlike the ureter, bladder urothelium is derived from endodermal cloacal tissues. Starting at E10.5, the cloaca becomes divided by the urorectal septum into a dorsal anorectal canal and a ventral urogenital sinus. At E11.5–12.5, the urogenital sinus further subdivides into an anterior

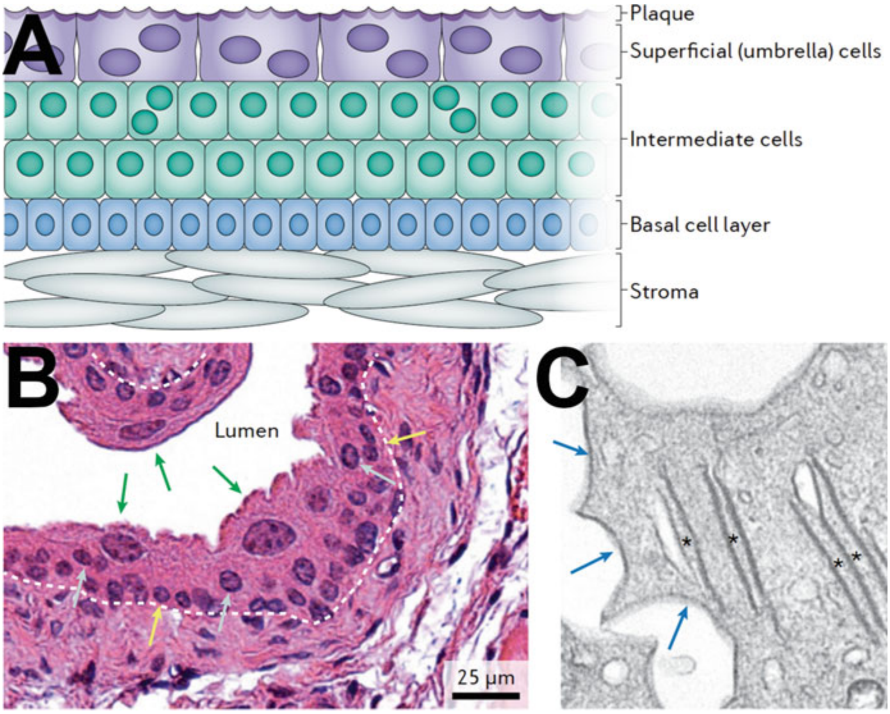

Fig. 7 **Structure of adult urothelium.** (**a**) Diagram showing the various cell layers of the mature urothelium, including Superficial cells that possess an apical plaque, Intermediate cells and Basal cells that sit on the stroma. (Reprinted by permission from Springer Nature. Jackson et al. [166], adapted from Figure 1)

portion, which will become the bladder, and a posterior portion that forms the urethra and parts of the female vagina. The mesenchyme that surrounds bladder urothelium is largely thought to be from splanchnic mesoderm, although fate-mapping studies reveal that tailbud mesenchyme also contributes to bladder mesenchyme (similar to the ureter) [165]. By E13.5, the bladder is recognized as a distinct structure that is attached directly to the ureters. As is the case with ureters, αSMA mRNA expression in the developing bladder muscle precedes protein expression; mRNA expression appears as early as E11.5 in mice [169], while protein expression begins at E13.5 [170]. Unlike the ureter (and many other organs with smooth muscle such as the intestine) that has a thin ring of mesenchyme that begins to differentiate into muscle, the entire outer half of the bladder mesenchyme condenses simultaneously and strongly expresses αSMA by E15.5 [169]. Similar to the ureter, bladder urothelium matures from a simple epithelium to a stratified epithelium, consisting of cell types similar to the ureter, including having Superficial cells and subsets of Intermediate cells that express uroplakins and urothelial plaques [166]. While bladder urothelial Basal cells were originally thought to be the progenitor cell for the other urothelial cell types, lineage tracing studies revealed the presence of a transient population of "P" cells that appear to serve as embryonic progenitors for uroplakin-expressing Intermediate and Superficial cells [166]. In contrast Keratin 5-expressing Basal and/or Intermediate cells appear to give rise to themselves and not uroplakin-expressing cells during development [166].

While the connection of the ureters with the bladder is critical, how this occurs has been the subject of some debate. What is clear is that between E12.5 and 13.5 in the mouse, the common nephric duct (caudal portion of the nephric duct between the ureter base and future bladder) moves adjacent to the bladder, allowing for the ureters and rostral nephric ducts (future male gonadal excretory ducts) to separate and empty directly into the bladder. The triangular portion of the bladder demarcated by the entry points of the ureters and the bladder neck (where the remaining embryonic nephric ducts empty) is known as the trigone. Historically the common nephric duct was thought to become incorporated into the bladder to form the trigone, given that the mature trigonal epithelium is smooth while the rest of the bladder urothelium has rugae [167]. However, fate mapping studies in mice revealed that the common nephric duct undergoes complete apoptosis starting at E12.5, and that the urothelium of the trigone originates entirely from bladder urothelium [167]. The conclusions from the fate mapping studies were supported by tissue studies comparing how mouse embryonic trigonal epithelium, nephric duct epithelium and bladder dome epithelia differentiated when combined with rat urogenital sinus mesenchyme and grown under kidney capsule; moreover, at the conclusion of the experiments, the trigonal epithelium expressed differentiation markers similar to bladder dome epithelium and not the nephric duct epithelia [167]. Regarding the origin of the mesenchymal cells underlying the bladder trigone, lineage tracing studies using Cre-/loxP techniques in mice showed that the muscle present in the trigone arises mostly from the bladder with only a few fibers emanating from ureteral muscle [167]. Thus, the trigone originates almost completely from bladder tissues and not the nephric duct.

Recently, a group of investigators identified the presence of modified urothelial cells that line the inner renal medulla (termed “intrarenal urothelium”) [166]. In the quiescent state, the intrarenal urothelium consists of one to layers of interspersed Uroplakin 3^+ and Keratin 5^+ cells and is devoid of urothelial plaques. With urinary tract obstruction, however, the intrarenal urothelium can proliferate and stratify, including generating large Superficial-like cells that have organized uroplakin-derived plaques. After genetic deletion of uroplakins in the intrarenal urothelium, mice subjected to urinary tract obstruction develop severe hydronephrosis and biochemical evidence of renal failure beyond what is seen in controls; this suggests a critical roles for the intrarenal urothelium with high urinary pressures. Fate mapping studies have shown that Keratin 5^+ cells serve as the embryonic progenitors for the uroplakin-expressing cells within the intrarenal urothelium. After postnatal day 14 in mice, Keratin 5^+ cells lose the potential to form uroplakin-expressing cells, except after urinary tract obstruction when the former are again able to give rise to the latter. Presently, signaling pathways required for morphogenesis of the intrarenal urothelium are unknown. However, many studies have identified molecules required for ureter and bladder development as will be discussed next.

Molecular Control of Ureter and Bladder Development

Ureter

The pathways critical for early ureteric bud formation were already covered in the section on kidney development above. Once the ureteric bud forms, the distal end matures into collecting duct epithelium while the proximal end (near the bladder) becomes ureter urothelium. Studies have shown that bone morphogenetic protein 4 (BMP4), which is secreted by tailbud derived mesenchyme surrounding the distal ureteric bud, drives the epithelium toward a urothelial fate; moreover, ectopic *Bmp4* expression around proximal portions of the ureteric bud directs it to become urothelium instead of collecting duct epithelium [165]. More recent work has shown that in addition to specification, BMP4 is required for ureter urothelial proliferation and differentiation, mostly via AKT signaling (with minor contributions from P38 kinase and ERK signaling) [171]. Another study identified the signaling pathway that drives BMP4 expression [172]. The growth factor Sonic hedgehog (SHH) is secreted by the ureteral epithelium and binds to its receptor, Patched 1, in surrounding mesenchyme. This in turn drives expression of the Forkhead transcription factor gene, *Foxf1*, that then stimulates BMP4 expression. Mutations in *SHH*, *FOXF1* and *BMP4* have been identified in some patients with renal and lower urinary tract anomalies, attesting to the clinical relevance of this signaling axis [166]. In addition to the SHH-FOXF1-BMP4 signaling axis, uroplakins, markers of urothelial maturation, are also critical for normal urothelial morphogenesis. Loss of either Uroplakin II or Uroplakin IIIa leads to severe urothelial plaque defects, hypoplastic Superficial cells, urothelial leakiness, hydronephrosis, and vesicoureteral reflux [165]. Moreover, mutations in *UPKIIIa* in humans have been associated with severe renal dysplasia and reflux [173], whereas the role of *UPKII* in humans is still unclear [174].

Many of the molecules critical for ureter mesenchymal patterning have also been identified. In addition to its role in ureter urothelial morphogenesis, Sonic hedgehog secretion by the urothelium is also critical for ureter mesenchyme development. Conditional ablation of *Shh* in developing mouse ureteric epithelium leads to loss of mesenchymal proliferation and smooth muscle differentiation [165]. Furthermore, SHH signaling from urothelium has also been shown to be critical for formation of *Hcn3* and *c-Kit* expressing pacemakers within the ureteral muscle, via the hedgehog signaling mediators Smoothened and GLI3 repressor [165]. In addition, the aforementioned SHH-FOXF1-BMP4 signaling axis is necessary for ureter mesenchyme proliferation and differentiation into muscle, especially at the ureterovesical junction [172]. The downstream signaling target of BMP4 most critical for ureter mesenchymal proliferation is AKT while the target most important for muscle differentiation is SMAD 1/5/9 (P38 kinase has minor roles in both) [171]. Finally, the transcription factor, Teashirt 3 (*Tshz3*), downstream of both SHH and BMP4, is critical for proximal ureteral smooth muscle differentiation and for normal ureteral peristaltic function; deletion of *Tshz3* in mice leads to severe muscle patterning defects and congenital hydronephrosis [165]. Thus, SHH signaling is critical for ureter mesenchyme morphogenesis.

Another signaling pathway that is critical for ureter mesenchyme patterning is the WNT- T-box (TBX) transcription factor signaling axis. WNT ligands are secreted by urothelium, bind to frizzled receptors in the mesenchyme and signal primarily by stabilization of β-catenin (CTNNB1). Investigators found that genetic ablation of *Ctnnb1* in mice led to decreased mesenchymal proliferation and differentiation into smooth muscle cells, with concurrent expansion of the outer adventitial fibroblast layer [165]. More recently other groups found that the transcription factors, TBX2 and TBX3 are critical WNT targets in ureter mesenchyme; the TBX proteins in turn suppress the WNT antagonists, DKK2 (Dickkopf 2), and SHISA2, and stabilize BMP4 expression by suppressing the BMP4 antagonist, BMPER (BMP binding endothelial regulator), together leading to proper ureter mesenchymal patterning and differentiation [175]. Another T-box transcription factor, TBX18 is also induced by WNT signaling and is required for ureter mesenchyme morphogenesis. Genetic ablation of *Tbx18* leads decreased levels of *Sox9* and to decreased proliferation and failure of smooth muscle differentiation, and ultimately severe hydroureteronephrosis [165]. Recently, investigators identified dominant negative mutations in *TBX18* in three families leading to renal and urinary tract anomalies including severe ureteropelvic junction obstruction (validating the role of TBX18 in human disease) [176].

Other signaling molecules have been shown to regulate ureter mesenchyme development. Studies in mice found that conditional ablation of the calcineurin b1 subunit in developing ureteral mesenchyme led to reduced smooth muscle proliferation and hydronephrosis [165]. Furthermore, genetic ablation of the angiotensin type 1 receptor (which is expressed in ureteral mesenchyme) caused smooth muscle hypoplasia, a lack of peristalsis, and ultimately hydronephrosis [165]. Retinoic acid (RA) receptor signaling has been shown to be critical for maintaining ureter mesenchymal progenitors, as reduced retinoic acid signaling leads to premature ureter smooth muscle differentiation [177]. Conversely, *Gata2*, a transcription factor in ureter mesenchyme that is induced by retinoic acid, appears to drive feedback inhibition of RA signaling; conditional deletion of *Gata2* in ureter mesenchyme led to a delay in ureter smooth muscle differentiation and hydroureter apparently from disinhibited retinoic acid receptor signaling [177]. Lastly, Discs-large homolog 1 (DLG1) is the only gene identified to date that is necessary for ureter lamina propria/stromal cell development; genetic deletion of *Dlg1* in mice led to an absence of the entire ureteral lamina propria layer and disorganized muscle development [178].

Bladder

Compared with the ureter, less is known about the molecular control of bladder development. Some of the pathways critical for formation of the urogenital sinus (future bladder) have been identified. Bidirectional signaling between Ephrin-B2 (ligand) and EPHB2/EPHB3 (tyrosine kinase receptors) is critical for septation of the cloaca into the ventral urogenital sinus and the dorsal anorectal canal [179]. Sonic hedgehog signaling is also critical for formation of the urogenital sinus. In mice, the loss of *Shh* or compound mutations in the downstream hedgehog mediators, *Gli2* and *Gli3,* lead to failure of cloacal septation [180]. During later stages of bladder formation, urothelial cell stratification is dependent on retinoid signaling emanating from the lamina propria surrounding the urothelium; forced expression of a dominant negative retinoic acid receptor in developing mouse urothelium leads to a loss of Superficial cells and subsets of Intermediate cells [166]. Finally, a recent study revealed that the EED (Embryonic Ectoderm Development) subunit of the polycomb repressive complex 2 (PCR2), which leads to transcriptional silencing of genes, is required for normal bladder urothelial morphogenesis [181]. Conditional deletion *Eed* in embryonic mouse urothelium led to reduced urothelial proliferation and differentiation defects, apparently due in large part to reduced *Shh* expression [181].

In addition to data on signaling necessary for bladder urothelial development, some of the genetic pathways critical for bladder mesenchyme development have been identified. As is true in the ureter, several studies have shown that SHH signaling from the bladder urothelium is necessary for bladder mesenchyme morphogenesis; loss of *Shh* in mice leads to a complete loss of bladder smooth muscle formation [167]. Moreover, the gradient of SHH signaling is critical for normal mesenchymal patterning; smooth muscle formation is inhibited in favor of collagen in the bladder mesenchyme nearest to the urothelium (where SHH signal is the strongest). In contrast, smooth muscle formation is stimulated in outer regions of bladder mesenchyme, where SHH signal is weaker [167]. Elegant studies have shown that co-culture of embryonic mouse bladders with fetal esophagus (which secretes high levels of SHH) leads to repression of muscle formation in the outer bladder mesenchyme that normally forms the detrusor muscle [167]. The differential effects of SHH signal intensity of the fate of bladder mesenchyme appears to be secondary to BMP4 signaling; SHH-Patched signaling induces BMP4 expression in the mesenchyme nearest the urothelium, which suppresses muscle formation, while bladder mesenchyme farthest from the urothelium is relatively devoid of SHH-induced BMP4 expression. Another study showed that fibroblast growth factor receptor 2 (FGFR2) expressed in bladder mesenchyme alters the sensitivity of the mesenchyme to SHH signals. Conditional loss of *Fgfr2* in mouse embryonic bladder mesenchyme led to an expansion of the collagen-rich lamina propria and loss of outer detrusor muscle [182]; loss of FGFR2 led to enhanced expression of *Boc* and *Cdo*, genes that encode for co-receptors that enhance SHH signaling through its Patched receptors. The postnatal mutant mice had poorly compliant bladders and severe voiding dysfunction.

Other molecules critical for bladder mesenchyme patterning have been identified. Transforming growth factor beta (TGF-β), which is in the same superfamily of signaling molecules as BMPs, appears critical for bladder muscle patterning. Chemical inhibition of TGF-β1 signaling suppressed bladder muscle formation in embryonic mice [167]. Another group has shown the importance of myocardin, a transcription factor, in bladder smooth muscle patterning [169]. The investigators generated random transgene insertional mutant mice called megabladder mice (*mgb-/-*) that have very limited αSMA expression in embryonic bladders, and ultimately develop massive bladders with no functional detrusor.

The group later found that the mouse has significantly reduced levels of myocardin. Importantly, the investigators recently identified four families with members afflicted with bladder smooth muscle defects leading to megabladders that have mutations in the myocardin gene, revealing the clinical relevance of the molecule [169].

Ureter-Bladder Anastomosis

There are some data on genetic pathways necessary for the proper connection between the ureter and bladder, i.e., apoptosis of the common nephric duct starting at E12.5 in mice. Retinoid signaling from the bladder has been shown to be critical for this process. Genetic ablation of retinaldehyde dehydrogenase-2, an enzyme expressed in the urogenital sinus and necessary for retinoic acid synthesis, led to persistence of the common nephric duct with ureters ending blindly in the nephric duct [167]. In addition, the receptor tyrosine kinase, RET, has also been shown to be essential for ureter-bladder anastomosis. Mice with a point mutation in tyrosine 1015, the phospholipase Cγ binding site on RET (*RetY1015*), have a persistent common nephric duct due to enhanced proliferation and decreased apoptosis [183].

Summary

Lower urinary tract defects contribute substantially to chronic kidney disease in children, necessitating a better understanding about the genes regulating lower urinary tract morphogenesis. While our understanding of the molecular control of ureter, bladder, and intrarenal urothelial development trails that of the kidney, more studies are emerging on how these tissues form.

Abstract

The kidney functions to maintain a constant volume and composition of the extracellular fluid volume. The glomerulus forms an ultrafiltrate of plasma which enters the proximal tubule where most of the fluid, organic solutes, and electrolytes are reabsorbed in an isotonic fashion. The more distal nephron segments are responsible for the final regulation of electrolyte and solute absorption and secretion as well as urinary concentration and dilution. Glomerulogenesis continues until 34–36 weeks gestation. The term neonate thus has a comparable nephron endowment as an adult. The term neonate has a much lower glomerular filtration rate than an adult even when factored for body surface area. There is postnatal maturation of the glomerulus and a parallel increase in tubular resorptive capacity. Transport occurs across tubules and also across the paracellular pathway. The very premature infant is far less equipped for life outside the mother's womb. There is glomerular tubular imbalance for infants less than 34 weeks as evidenced by glucosuria and very premature infants filter far more sodium than they can recover resulting in renal salt wasting. Postnatal maturation is much more complex than originally thought. There is not only a maturational increase in transporter abundance but there are changes in isoforms of key renal transporters during development as well as change in the paracellular pathway. This chapter discusses the postnatal changes in glomerular filtration rate and tubular transport of solutes and water that occur in the term and preterm neonate.

Renal development · Tubule transport · Glomerular filtration rate · Urinary concentration · Urine dilution · Nephron

Maturation of GFR

The neonate GFR is ~20–40 mL/min/1.73m^2 at birth in term infants and even lower in preterm infants [1–4]. GFR approximately doubles in the first 2 weeks of life in term infants but does not reach adult levels until 2 years of age [4, 5]. In infants with very low birth weight, adult level GFR may not be reached until 8 years of age [6]. Preterm infants have a sharp increase in GFR once nephrogenesis is complete after 34–36 weeks [7]. In all neonates (term and preterm), postnatal increases in GFR result from increases in renal blood flow and regulation of renal vascular resistance.

Cardiac output to the kidney increases from 3% to 10–15% in the first week to 1 month of life and then to adult levels of 20–25% by 2 years of age [7–9]. Mean arterial blood pressure also increases immediately after birth, which increases the hydrostatic pressure in glomerular capillaries. Together, increased cardiac output and increased mean arterial pressures lead to a significant increase in renal plasma flow rate in the first weeks of life. For the glomeruli to appropriately receive this increased renal flow and thus increase GFR, regulation of renal vascular resistance is crucial.

Perfusion of the glomerular capillary network of the glomerulus comes via the afferent arteriole and blood exits via the efferent arteriole. Local and systemic mediators of vasodilation and vasoconstriction act upon the afferent and/or efferent arterioles to mediate renal vascular resistance and thus glomerular perfusion and GFR. Vasodilation of the afferent arteriole and vasoconstriction of the efferent arteriole increases GFR. Conversely, vasoconstriction of the afferent arteriole and vasodilation of the efferent arteriole decreases GFR. The most important mediators leading to increase in GFR after birth are angiotensin II and prostaglandins. Angiotensin II, part of the renin-angiotensin system, acts primarily to vasoconstrict the efferent arteriole to increase glomerular pressure [10]. This helps to offset the relatively lower mean arteriole pressure of neonates to ensure adequate renal perfusion for filtration. Angiotensin II also increases systemic blood pressure via increased peripheral resistance and increases myocardial contractility to increase cardiac output [11], both of which contribute to increased renal perfusion and GFR. Prostaglandins vasodilate the arterioles. The role of prostaglandins is to offset or balance vasoconstrictive effects of hypotension, hypovolemia, and hyponatremia [12]. Both angiotensin II and prostaglandins are abundant shortly after birth [12].

Other regulators of renal arteriole vasodilation include nitric oxide, atrial natriuretic peptide (ANP), and bradykinin. Nitric oxide is a potent vasodilator that counterbalances the vasoconstrictive action of angiotensin II. Animal models show that nitric oxide synthase enzymatic activity is higher in the newborn compared to adults and plays a critical role in protecting the neonatal kidney from acute hypoxemia [13, 14]. ANP is produced by atrial myocytes in response to increased arterial volume or pressures. ANP vasodilates afferent arterioles, contributing to an increase in GFR [15]. Bradykinin is a vasodilator and its receptors are more prevalent in neonatal kidneys compared to adult kidneys [16].

Additional regulators of renal arteriole vasoconstriction are endothelin and the sympathetic nervous system. Endothelin is produced by the vascular endothelium and constricts the afferent and efferent arterioles, decreasing GFR when present at high levels. Conversely, low concentrations of endothelin present in physiologic conditions in the neonate may vasodilate the glomerular vessels [17]. Sympathetic nerves secrete norepinephrine, which constricts both afferent and efferent arterioles [18].

Adenosine vasoconstricts the afferent arteriole and vasodilates the efferent arteriole via stimulation of the angiotensin II receptor, which leads to decreased GFR if unopposed [1]. In physiologic conditions, adenosine carefully balances the efferent vasoconstrictive action of angiotensin II to maintain glomerular pressure and GFR. In pathologic conditions such as hypoxia or hypotension, excess generation of adenosine may lead to increased afferent arteriole vasoconstriction and decreased GFR [8]. Adenosine antagonists, such as theophylline or caffeine, protect against reduced GFR in term neonates with birth asphyxia [19] and in preterm neonates [20].

Autoregulation and tubuloglomerular feedback also affect vascular tone and GFR maturation [21, 22]. Autoregulation maintains constant renal blood flow despite mean arterial blood pressure fluctuations by altering arteriolar tone. Arteriole vasoconstriction in response to lower perfusion pressures seen in the neonate compared to the adult is the result of prostaglandin-dependent renin release [23]. Tubuloglomerular feedback is the means by which vascular tone responds to fluctuations in luminal sodium concentrations sensed by the macula densa and juxtaglomerular cells. For example, when blood pressure is low there is less sodium delivery so juxtaglomerular cells stimulate angiotensin II to constrict the efferent arteriole and maintain intraglomerular pressure and GFR. Adenosine counterbalances the efferent vasoconstrictive action of angiotensin II in tubuloglomerular feedback.

Overall, renal vascular resistance is elevated at birth and decreases in the first few weeks of life; this along with increased systemic blood pressure and increased cardiac output to the kidney leads to increased renal blood flow and GFR.

Measuring GFR in the Neonate

While inulin is the “gold standard” for measuring GFR in infants, it is not readily available clinically; thus, serum creatinine and cystatin C are more often used to measure GFR in neonates. Serum creatinine is the most commonly used marker of kidney function in the neonate, but has limitations. Serum creatinine reflects maternal creatinine for the first few days of life due to passive transport across the placenta and is reabsorbed by the immature tubules; thus, creatinine-based formulas can be inaccurate for neonates [24, 25]. Cystatin C has minimal transport across the placenta and a review of ten studies evaluating cystatin C GFR in neonates showed that cystatin C levels are not affected by the infant's gender, gestational age, or muscle mass [26]. Furthermore, cystatin-C based GFR equations have been validated in infants and children, including preterm infants [27, 28]. Post-conceptual age affects both cystatin C and creatinine levels, however, which should be accounted for when evaluating neonatal GFR [29].

Preterm Neonate Nephron Development and GFR

Nephrogenesis ends at 34–36 weeks gestation. The term neonate has between 200,000 and 2,000,000 nephrons per kidney [8]. The nephrons mature and hypertrophy until reaching adult size between 3 and 5 years of age [30]. In preterm infants, nephrogenesis can continue for up to 40 days after birth, so it is crucial to optimally support this process by avoiding kidney injury from nephrotoxic medications and hypotension in the first several weeks of life [12]. The number of nephrons increases by approximately 25,000 for each 100 g of birth weight [31]. Birth weight less than 1000 g was the only neonatal characteristic associated with lower eGFR in children aged 3–10 [32], suggesting that the premature, low birth weight infant is at the most risk for renal damage in the neonatal period.

Inulin clearance studies show that normally GFR increases from 28 to 36 weeks gestation, when glomerulogenesis is completed, and then plateaus until birth [2, 3, 33]. For those born preterm, GFR increases in the first week of life but not as rapidly as in the term neonate [34]. Serum creatinine also does not decrease as quickly in the first week of life in preterm infants, often taking up to 1–3 months to reach its nadir [33, 35]. In the preterm infant, GFR increases more rapidly and serum creatinine decreases more rapidly at 34–36 weeks post-conceptual age, correlating to glomerulogenesis completion [35].

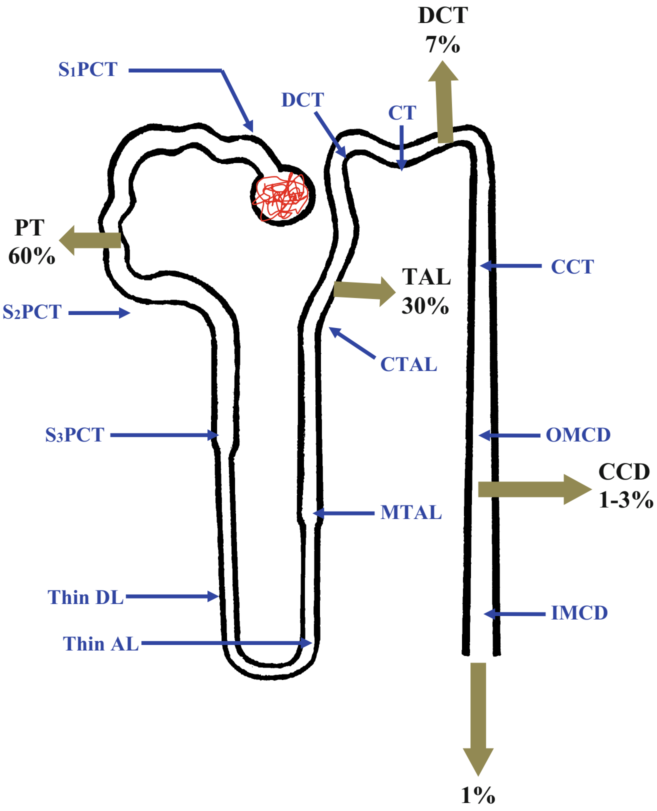
Organization of the Tubular Nephron

The nephron is faced with the task of maintaining a constant composition and volume of the extracellular fluid. The adult ingests electrolytes, nutrients, and water, and generates waste products that must be eliminated to maintain a constant composition and volume of the extracellular fluid compartment. In other words, the quantity of electrolytes that are ingested and absorbed must be eliminated and the waste products from metabolism must be also be excreted. This challenge is all the more complex as our dietary intake is quite variable from day to day. Despite this variable intake, there is virtually no change in the volume or composition of the extracellular fluid volume.

There are two possible ways that our kidney could balance ingestion and excretion. The kidney could be a secretory organ where all the excess electrolytes, solutes, and water ingested would be excreted by tubular secretion. This would be very inefficient and require an enormous amount of energy. In addition, in times of a disturbance in the extracellular fluid volume such as a high salt intake or volume loss from diarrhea, for example, the regulatory systems necessary to maintain a constant extracellular fluid volume and composition while excreting waste products would be very complex. In contrast, the kidney could filter an enormous quantity of extracellular fluid, which would be very efficient in removing waste products, and reclaim the desired salt, organic solutes, and water. With volume depletion, a greater fraction of salt and water could be reabsorbed and when one has a dietary indiscretion such as the salt intake from a pepperoni pizza, there could be a reduction in sodium reabsorption leading to an increase in excretion of salt to bring us back into balance. The mammalian kidney actually uses both mechanisms to maintain a constant composition and volume of the extracellular fluid which is necessary for survival on land. The adult kidney filters ~150 l of isotonic fluid a day and reclaims most of it, leaving the non-reabsorbed waste and salts to be excreted in about 1.5 l of urine. In addition, there are secretory processes for solutes such as organic anions and cations in the proximal tubule and mechanisms to secrete the excess acid generated from metabolism in the distal nephron which aid in maintaining homeostasis.

To accomplish the remarkable task of reclamation of the necessary solutes and water to maintain a constant composition of the extracellular fluid volume, the mammalian kidney has evolved into a highly specialized organ with thousands of units called nephrons. Each human kidney has approximately one million nephrons. Each nephron is a tube consisting of epithelial cells and is divided into 12 specialized segments as shown in Fig. 1. The epithelial cells allow for the vectorial transport of solutes. The proximal tubule is responsible for the bulk reclamation of solutes and water and for the secretion of organic cations and anions. Approximately two-thirds of the glomerular filtrate is reabsorbed by the proximal tubule in an isotonic fashion. Virtually all of the organic solutes, as well as the majority of bicarbonate, phosphate, and chloride are reabsorbed in this segment. The proximal tubule is divided into S_1, S_2, and S_3 segments based on the rates of transport of some solutes, and morphological changes that occur down the proximal tubule. The proximal tubule transitions into the thin descending limb which can be of variable length and then makes a hairpin turn into the thin ascending limb which aids in the generation of a concentrated urine. The length of the thin ascending and descending limb is variable among species with dessert rodents having very long thin limbs as they need to

Fig. 1 This cartoon depicts the nephron with its 12 segments. Shown in blue are the nephron segments. S_1, S_2, S_3 PCT depict the three segments of the proximal tubule. The loop of Henle consists of the thin descending limb (thin DL) and thin ascending limb (thin AL) and the medullary (MTAL) and cortical thick ascending limb (CTAL). The distal convoluted tubule (DCT) is comprised of the connecting tubule (CT) and the initial cortical collecting tubule. The collecting duct is made up of the cortical collecting tubule (CCT), outer medullary (OMCD), and inner medullary collecting duct (IMCD). Shown in black is the percentage of sodium reabsorbed by the proximal tubule (PT), thick ascending limb (TAL), distal convoluted tubule (DCT), and cortical collecting duct (CCD). Typically, 1% of the filtered sodium is excreted



conserve water and excrete very concentrated urine. The length of the thin ascending and descending limbs increase as one goes from the superficial cortex down to the medulla. The thin descending limb expresses aquaporin 1, a water channel, on the apical and basolateral membranes making the thin descending limb very permeable to water [36]. This segment does not actively transport solutes and has a very low solute permeability. This results in a concentrated fluid in the medulla with a very high sodium chloride content in the luminal fluid providing a passive driving force for sodium chloride diffusion out of the thin ascending limb. The thin ascending limb is impermeable to water but has a high permeability to NaCl [37]. The chloride channel (CLC-K1) in the thin ascending limb is developmentally regulated [38]. There is no expression of CLC-K1 in the fetus and in the first few days of life until the end of the first week in rats. There is a correlation between CLC-K1 and urinary osmolality suggesting an important role of this channel in generating a hypertonic medulla [38]. Diffusion of NaCl causes a high interstitial osmolality. This loop structure along with the thick ascending limb generates the countercurrent multiplication system that results in a medullary osmolality far greater than that of blood [39, 40]. The importance of passive properties of the thin limbs in this countercurrent system is exemplified in mice which are deficient in aquaporin 1 [41]. The urine osmolality of aquaporin 1 deficient mice is greater than plasma, but far less than control mice that have normal aquaporin 1 expression [41]. In addition, aquaporin 1 knockout mice cannot increase their urine osmolality in response to water deprivation unlike control mice.

The thick ascending limb is the segment responsible for ~30% of sodium chloride transport and has a vital role in generating a concentrated medulla. Apical sodium chloride absorption is mediated by the bumetanide sensitive cotransporter. One of the unique features of this segment is the fact that it is impermeable to water and thus the fluid leaving this segment is hypotonic to blood. In addition, this segment has a very high paracellular permeability to cations and is responsible for much of calcium and magnesium reabsorption. The distal convoluted tubule is responsible for ~5–10% of NaCl transport. NaCl transport in this segment is mediated by the thiazide-sensitive cotransporter. Active transcellular calcium and magnesium transport also occurs in this segment.

The rest of the distal tubule is separated into the connecting tubule and the cortical, outer, and inner medullary collecting tubule. These segments are responsible for sodium absorption, potassium secretion, final urinary acidification, and water absorption; the latter is regulated by vasopressin, which causes the insertion of aquaporin 2 water channels into the apical membrane. While the fraction of salt transport and renal acidification by the collecting tubule (or collecting duct) is a small fraction of the capabilities of some of the upstream nephron segments, the collecting tubule is responsible for the final modulation of the tubular fluid. Thus, the final composition of urine and significant regulation of transport occur in these last segments.

Principals of Membrane Transport

The cells along the nephron are quite different in the various nephron segments, which will be discussed in the subsequent sections. The cells in each nephron segment are poised for vectorial transport. The apical and basolateral membranes are, by and large, a lipid bilayer which would be impermeable to water and solutes if there were not specific proteins to facilitate transport across the apical and basolateral membranes. In addition, many transporters are regulated to adjust their rate of transport to meet the physiologic changes in volume status or concentration of solutes in the extracellular milieu.

The reabsorption of solutes along the nephron is characterized by active and passive transport processes. A typical cell (proximal tubule cell) is shown in Fig. 2. If all active transport was inhibited along the nephron, we would excrete urine with the composition and volume of the glomerular ultrafiltrate. Passive transepithelial transport is, by and large, the result of gradients generated by active transport. Most active transport is the result of the basolateral Na^+,K^+-

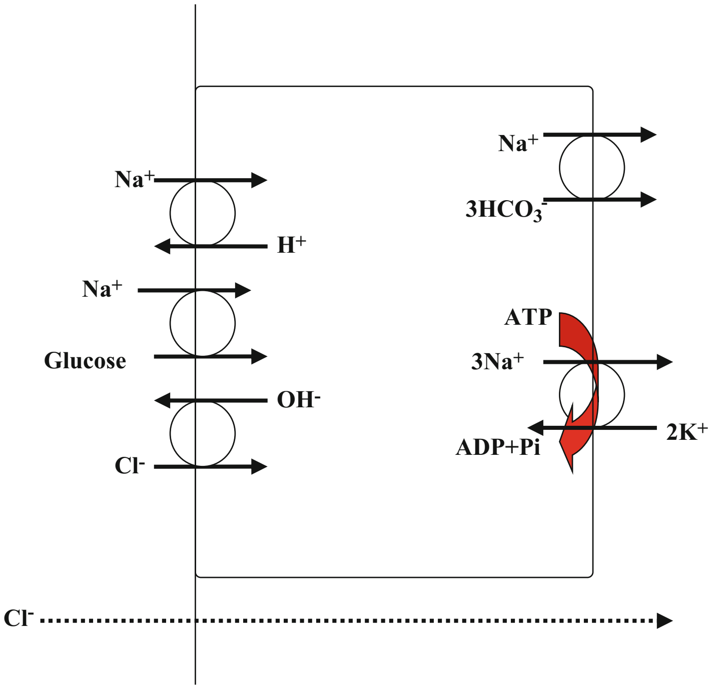


Fig. 2 A proximal tubule renal cell which shows the Na^+, K^+-ATPase on the basolateral membrane, an example of primary active transport. Na^+,K^+-ATPase decreases the intracellular sodium to about 10 mEq/l and increases the intracellular potassium to approximately 140 mEq/l. The pump is electrogenic with a cell negative potential of about 60–90 mV. The sodium gradient provides the driving force for the apical Na^+/H^+ exchanger and both the sodium gradient and the potential difference provide the driving force for the apical sodium glucose transporter. The secretion of protons via the Na^+/H^+ exchanger results in the driving force for the Cl^-/OH^- exchanger which is an example of tertiary active transport. Chloride is shown traversing the paracellular pathway. Bicarbonate is exiting the basolateral membrane via a sodium bicarbonate cotransporter

ATPase. This transporter pumps three sodiums out of the cell in exchange for two potassium ions. The pump utilizes ATP and it is an example of primary active transport. This pump is vital to the generation of the low intracellular sodium and high intracellular potassium concentration as well as the negative intracellular potential difference across the apical and basolateral membranes. Both the low intracellular sodium and this potential difference can provide a driving force for secondary active transport. For example, in Fig. 2, the reabsorption of glucose via a sodium-dependent transporter utilizes both the sodium gradient and the relative negative cell potential to bring glucose in the cell. The Na^+/H^+ exchanger on this cell is electroneutral and utilizes the sodium gradient to secrete protons and reabsorb sodium. Both the sodium glucose and the Na^+/H^+ exchanger are secondary active transport processes dependent on the basolateral Na^+,K^+-ATPase. The secretion of protons will cause the luminal pH to drop providing a favorable driving force for the Cl^-/OH^- exchanger, an example of tertiary active transport. Thus, in secondary and tertiary active transport, the transporters do not utilize ATP directly; however, inhibition of the ATP dependent Na^+,K^+-ATPase would bring these transport processes to a halt.

In addition to active transport a substantive amount of passive transport occurs between cells across the tight junction. Active transport along the nephron will generate ion and solute gradients between the lumen and peritubular fluid. Depending on the permeability properties of the tight junction, passive absorption or secretion can occur. In the cell depicted in Fig. 2, there is passive chloride transport across the paracellular pathway. It has become apparent that the characteristics of the tight junctions vary along the nephron. The tight junction creates the primary permeability barrier to diffusion of solutes across the paracellular pathway. Occludin and claudin proteins are localized to junctional fibrils and are transmembrane components of tight junctions [42–44]. These tight junction fibrils or strands are a major factor determining the permeability properties of the paracellular pathway [44–46]. The claudin family of tight junction proteins now numbers 24. Occludin has a ubiquitous distribution and is not responsible for the differential permeability properties in the various nephron segments. The claudin isoforms present at the tight junction of various epithelia determine the resistance and the permeability properties of the epithelia [44–46]. The distribution of claudin isoforms varies along the nephron and is responsible for the unique permeability properties of each nephron segment.

The final form of passive transport is called solvent drag. Solvent drag has been postulated to be responsible for a small fraction of transport in the proximal tubule. The reabsorption of solutes could result in water movement that could entrain or carry solutes with it. For this to occur, the solute would have to have a low reflection coefficient or high sieving coefficient (sieving coefficient = 1/refection coefficient). In other words, when a solute is entrained in fluid and hits a membrane or tight junction, it could pass through it and be transported across or bounce off and not be transported. Direct measurements of solute drag in the proximal tubule of neonates and adults have shown that it contributes a negligible fraction to transport [47–50].

Maturation of Na^+,K^+-ATPase Along the Nephron

The Na^+,K^+-ATPase is located on the basolateral membrane of most tubules in the kidney [51]. The Na^+,K^+-ATPase is a heterodimer composed of an α and β subunit. There are four different α subunits and three beta subunits on mammalian cells which have different functional properties [52]. There is also evidence for a small γ subunit that is not required for Na^+,K^+-ATPase activity on some cells [52, 53]. The γ subunit binds to the α subunit, stabilizes the enzyme, and plays a regulatory role in enzyme activity [52, 53]. The adult kidney expresses the α1 and ß1 isoforms of the Na^+,K^+-ATPase [54, 55]. The α subunit is the catalytic subunit and has the cation, ATP, and ouabain binding sites [52]. The β subunit is the regulatory subunit and is essential for the function of the enzyme [52, 56]. Several hormones that regulate sodium transport along the nephron act, at least in part, by regulating the Na^+,K^+-ATPase activity [52, 57–69]. Dopamine and atrial natriuretic factor inhibit, while alpha agonists and angiotensin II stimulate Na^+,K^+-ATPase activity [51]. Hormones such as dopamine directly regulate the Na^+,K^+-ATPase and do not act on transporters on the apical membrane [69].

The Na^+,K^+-ATPase is responsible for lowering the intracellular sodium concentration and establishing the negative cell potential difference. The Na^+,K^+-ATPase provides the driving force for sodium transport across the nephron. As shown in Fig. 3, there is a direct relationship between sodium transport and Na^+,K^+-ATPase activity factored per millimeter of tubule along

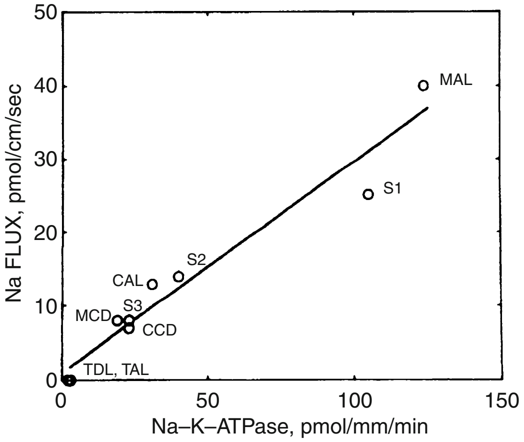

Fig. 3 Sodium transport is plotted against Na^+,K^+-ATPase activity. As is shown the rate of sodium transport in various nephron segments parallels Na^+,K^+-ATPase activity. *CAL* cortical thick ascending limb, *CCD* cortical collecting duct, *MAL* medullary thick ascending limb, *MCD* medullary collecting duct, *S1–3* S1–3 segments of the proximal tubule, *TAL* think ascending limb, *TDL* thin descending limb

the nephron [70]. Indeed, an increase in intracellular sodium concentration increases Na^+,K^+-ATPase activity [71]. Neonates have a lower renal Na^+,K^+-ATPase activity than do adult kidneys [68, 72–76]. As will be discussed, there is a developmental increase in sodium transport in each nephron segment, which is paralleled by an increase in Na^+,K^+-ATPase activity as shown in Fig. 4.

The parallel maturational increase in sodium transport with Na^+,K^+-ATPase activity [73] along with the striking relationship between sodium transport and Na^+,K^+-ATPase activity [70], suggests that the maturational increase in apical sodium transport may contribute to the postnatal increase in Na^+,K^+-ATPase. In cell culture studies, an increase in intracellular sodium resulted in a stimulation in Na^+,K^+-ATPase activity [77, 78] as well as an increase in the α subunit mRNA and membrane Na^+,K^+-ATPase density on the basolateral membrane [79]. In addition to in vitro studies, there is evidence that a chronic increase in Na^+/H^+ exchanger activity induced by metabolic acidosis, which could result in an increase in intracellular sodium, stimulated basolateral Na^+,K^+-ATPase activity, an effect that was blocked by coadministration of the Na^+/H^+ exchange inhibitor, amiloride [80]. Finally, there is a postnatal increase in both serum thyroid hormone and glucocorticoid levels with age [81–84]. Both hormones have been shown to increase Na^+,K^+-ATPase activity [58, 76, 85–88]. An in-depth discussion of the developmental expression, characteristics, and regulation of the Na^+,K^+-ATPase was presented in the Homer Smith award to Dr. Anita Aperia [6].

Proximal Tubule Transport

Proximal tubule transport is characterized by a phenomenon called threshold, which is depicted on Fig. 5. It is the threshold that keeps our serum bicarbonate at 25 mEq/L. If we were to ingest bicarbonate and try to raise our serum bicarbonate level, we would have a bicarbonaturia and our serum levels would return to 25 mEq/L as long as we were euvolemic. Our serum glucose is set by other factors well below the threshold level. As shown in Fig. 5, if we increased the serum glucose level, we would reabsorb more glucose until the load of glucose delivered to the proximal tubule exceeded its ability to reabsorb glucose and we would have glucosuria.

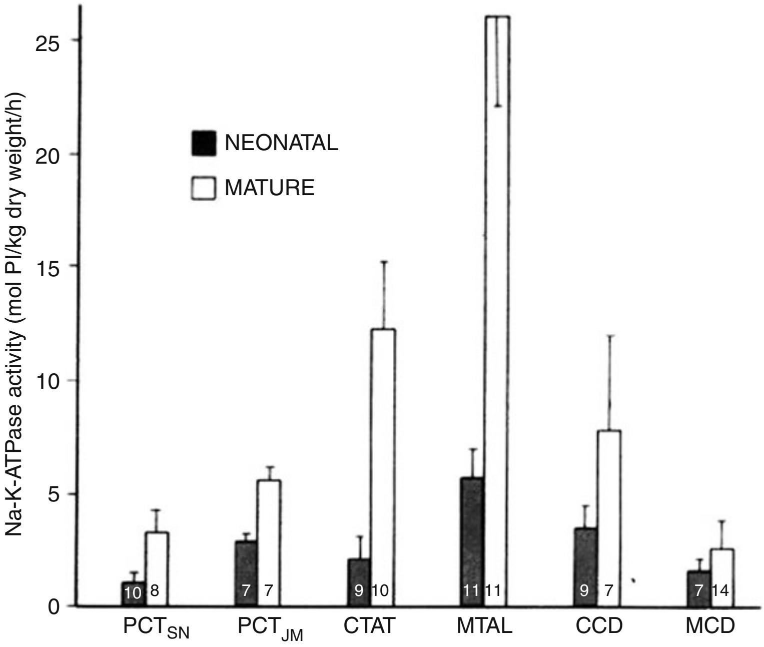

Fig. 4 Na^+,K^+-ATPase activity is shown in nephron segments of neonates and adults. As is demonstrated, there is a maturational increase in Na^+,K^+-ATPase activity in every nephron segment. PCT_{SN} proximal convoluted tubule from superficial nephrons, PCT_{JM} proximal convoluted tubule from juxtamedullary nephrons, *CTAL* cortical thick ascending limb, *MTAL* medullary thick ascending limb, *CCD* cortical collecting duct, *MCD* medullary collecting duct

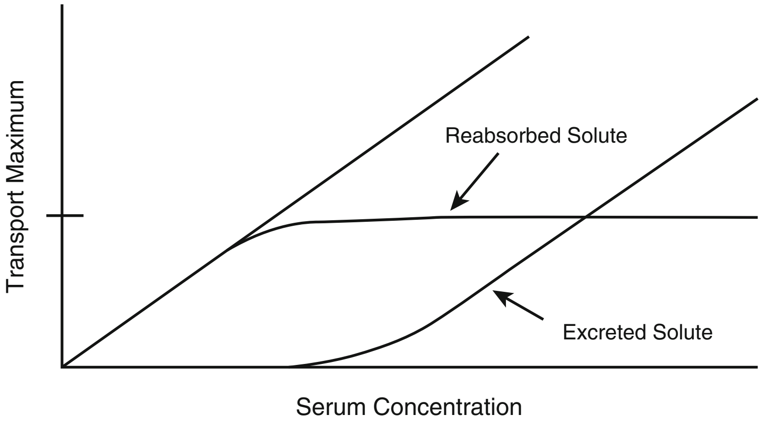

Fig. 5 Diagram depicting the concept of renal threshold. As the delivered solute load increases either by an increase in the serum concentration or an increase in glomerular filtration rate, the amount of solute absorbed increases. At some point, the renal tubular absorption reaches a maximum, called the threshold for that solute, and any further increase in the filtered load is excreted

In the adult kidney, there is a parallel change in proximal tubule transport with alterations in glomerular filtration rate. This phenomenon has been designated glomerular tubular balance. If the rate of proximal tubular transport was fixed, an increase in glomerular filtration rate would swamp the distal nephron with solutes and water and there would be a huge natriuresis and diuresis. A similar phenomenon must occur during postnatal development where there is a developmental increase in glomerular filtration rate. If there was not a parallel increase in proximal tubule transport with the maturational increase in glomerular filtration rate, the neonate would die of dehydration when the glomerular filtration rate increased after birth.

While during postnatal development there is a concomitant increase in tubular transport to accommodate or balance the increase in glomerular filtration rate [89–91], glomerular tubular balance is not present in the fetus [92]. Renal development is characterized by centrifugal maturation. The surface nephrons are relatively immature compared to the juxtamedullary nephrons. These immature nephrons with short proximal tubules have glomerular tubular imbalance [92]. This is clinically relevant as neonates born before 34 weeks gestation can have glucosuria and very premature neonates can have significant renal salt wasting [93].

The proximal tubule reabsorbs 60% of the glomerular filtrate in an isosmotic fashion. Due to the fact that the proximal tubule has a relatively high permeability to many ions, even solutes which are not actively transported by this segment may be absorbed by diffusion across the paracellular pathway. For example, since the proximal tubule reabsorbs over half of the glomerular filtrate, the luminal concentration of a solute such as magnesium, which is not actively transported by this segment, would increase over twofold. However, this does not happen because as the magnesium concentration rises above that in the peritubular capillaries, magnesium is passively reabsorbed across the paracellular pathway down the concentration gradient generated by the reabsorption of other solutes.

Glucose Transport

Glucose is reabsorbed solely by the proximal tubule (see ▶ Chap. 39, "Aminoaciduria and Glycosuria in Children"). Physiologic studies have demonstrated that the S_1 proximal tubule reabsorbs glucose by a high capacity, low affinity transporter, while in the late proximal tubule (S_3), glucose transport is via a low capacity, high affinity transporter [94]. Similar axial heterogeneity of glucose transport kinetics was validated using cortical brush border membrane vesicles to measure apical membrane transport and outer medullary brush border membrane vesicles which contain vesicles from the S_3 segment [95]. The high capacity, low affinity sodium-dependent glucose transporter on the apical membrane is designated SGLT-2 [96]. This transporter removes the bulk of the glucose from the glomerular ultrafiltrate. The low capacity, high affinity transporter is designated SGLT-1 and reabsorbs the glucose not reabsorbed in the early proximal tubule [97, 98]. The glucose that is transported into the tubule exits across the basolateral membrane by facilitative diffusion via GLUT2. Mutations in GLUT2 lead to Fanconi-Bickel syndrome [99, 100]. As shown in Fig. 6, SGLT-2 transports one sodium with one glucose molecule while SGLT-1 transports two sodium with each glucose molecule. A defect in SGLT-1 causes glucose-galactose malabsorption as this transporter is also present in the intestine [101–104]. Some patients with familial glucosuria, a benign condition, have a mutation in SGLT-2 [105, 106]. This axial arrangement of glucose transporters, where there is a high capacity, low affinity transporter followed by a low capacity, high affinity glucose transporter, results in reabsorption of virtually all of the filtered glucose.

Sodium-dependent glucose reabsorption results in a positive charge entering the proximal tubule cell. This charge leaves a lumen negative trans-epithelial potential difference. This negative potential provides a driving force for the absorption of an anion (chloride) or the back diffusion of a cation (sodium) across the paracellular pathway. Thus, glucose transport can result in a net absorption of sodium chloride with sodium moving into the cell with glucose and chloride across the paracellular pathway. Whether sodium is recycled back into the lumen or chloride is reabsorbed across the paracellular pathway is dependent on the relative sodium/chloride permeability of the paracellular pathway.

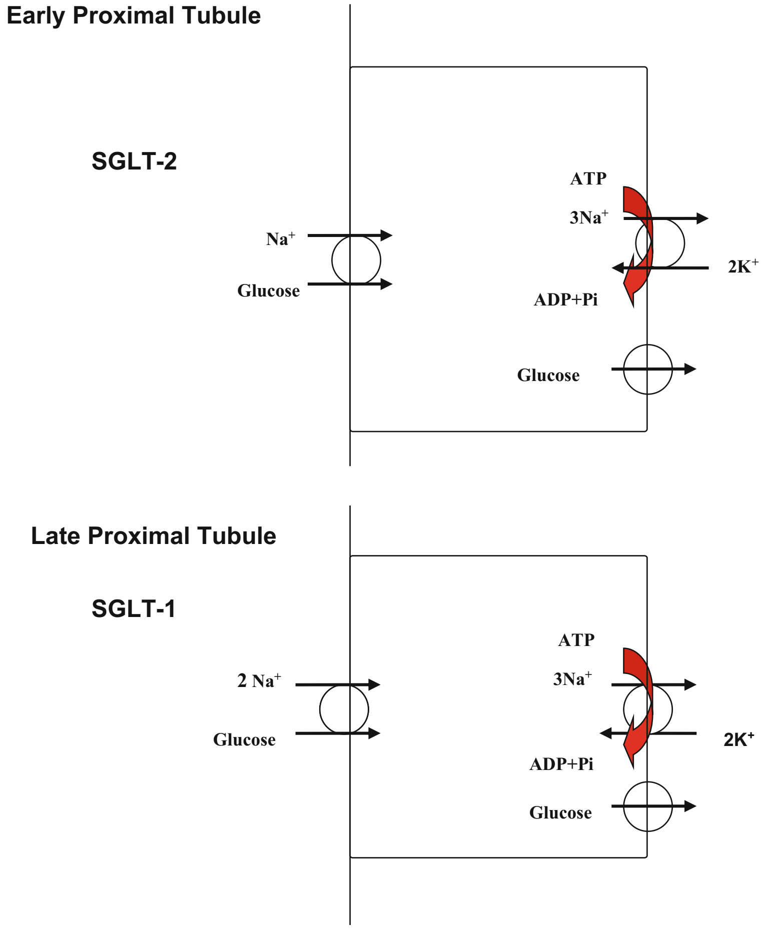

Fig. 6 Diagram of glucose transport in the proximal tubule. The early proximal tubule has SGLT-2 on the apical membrane which is a high capacity, low affinity transporter. The late proximal tubule has a low capacity, high affinity transporter designated SGLT1 on the apical membrane. Glucose exits the cell across the basolateral membrane by passive diffusion

Numerous studies using various techniques and animal species have shown that the fetus and neonate transport glucose at a slower rate than the adult [92, 107–110]. These studies are of clinical relevance as premature neonates can have glucosuria [93, 111, 112]. Despite the fact that the glomerular filtration rate of a premature neonate is about 1% of that of an adult and thus the filtered load delivered to the neonatal proximal tubule is also about 1% of that of the adult, the filtered load can exceed the resorptive capacity for glucose transport in the premature neonate. Thus, there is a time during development where glomerular tubular balance is not present. Kinetic studies demonstrate that the Km (the glucose concentration at half maximal velocity) for the glucose transporter is comparable between the fetus and adult, however the Vmax (maximal rate of glucose transport) is much lower in the neonate [113]. This indicates that the developmental increase in transport is not due to a glucose transporter isoform change but due to a maturational increase in the number of glucose transporters on the apical membrane.

Amino Acid Transport

All renal amino acid transport occurs in the proximal tubule (see ▶ Chap. 39, “Aminoaciduria and Glycosuria in Children”). Unlike most cells that have amino acid transporters to provide substrates for protein synthesis, the proximal tubule mediates the vectorial transport of amino acids from the filtrate to the blood. The basic principal for transport is similar to glucose transport. The uptake of amino acids is sodium dependent and electrogenic with the basolateral exit mediated by facilitated passive diffusion. While there are 20 amino acids that are utilized in the synthesis of proteins, there are not 20 different amino acid transporters on the apical and basolateral membranes. Since some amino acids are similar in structure and/or charge, there is promiscuity among the classes of amino acid transporters. We will briefly discuss the three major classes of amino acid transporters.

The neutral amino acids include leucine, valine, isoleucine, methionine, phenylalanine, tyrosine, cysteine, glutamine, alanine, glycine, serine, histidine, tryptophan, and proline. Transport of these amino acids is electrogenic with one sodium ion being transported with an amino acid across the apical membrane. B^0AT1 (SLC6A19) and is expressed on the proximal tubule [114–116] and transports all neutral amino acids, although there is greater affinity for valine, leucine, isoleucine, and methionine [117]. Mutation of SLC6A19 causes Hartnup disease which is an autosomal recessive disorder of variable severity characterized by a pellagra-like rash, cerebellar ataxia psychological and neurological disturbances [115, 116, 118]. The expression of B^0AT1 on the apical membrane is dependent on a protein called collectrin (Tmem27) [119]. A mutation and loss of collectrin also results in a Hartnup phenotype [120]. The symptoms due to Hartnup disorder are likely the result of impaired intestinal and renal transport of tryptophan [121]. There are other neutral amino acid transporters but their transport properties have been less well characterized [118, 122].

The acidic amino acids are aspartate and glutamate. They are transported across the apical membrane of the proximal tubule in an electrogenic fashion where two sodium ions are transported for each of these negatively charged amino acids [123, 124]. Brush border membrane vesical studies have shown that there are at least two apical transporters for glutamate, one with a high substrate affinity and one with a low affinity [125]. The high affinity transporter has been cloned and designated SLC1A1 (EAAC1) [126]. SLC1A1 is expressed on the apical membrane of the proximal tubule [127]. *Slc1a1* knockout mice have a dicarboxylic aciduria proving the importance of this transporter in acidic amino acid transport [128]. Recently, patients with SLC1A1 mutations have been found to have dicarboxylic aminoaciduria and mental retardation likely due to the importance of SLC1A1 for glutamate transport in the brain [129]. The basolateral transport of glutamate is via a sodium-dependent cotransporter indicating that the intracellular glutamate levels must be very high in the proximal tubule to provide an adequate driving force for sodium exit across the basolateral membrane [130]. In addition, there is a sodium independent aspartate/glutamate transporter which is localized to the basolateral membrane designated AGT1 [131].

The basic amino acids lysine and arginine utilize the same amino acid transporter as cystine and ornithine (COLA). Cystine, lysine, arginine, and ornithine are transported across the apical membrane of the proximal tubule by a heterodimer of two proteins designated rBAT (SLC3A1) and b^{o+}AT (SLC7A9). rBAT is a cystine/dibasic amino acid transporter expressed along the proximal tubule but predominantly in the S_3 segment [132, 133]. Mutations in rBAT (SLC3A1) results in type I cystinuria [134–137]. Mutations in B^{0+}AT which is also a cystine transporter/dibasic amino acid transporter causes type II cystinuria [138, 139]. While there is increased excretion of cystine, arginine, lysine, and ornithine in patients with cystinuria, cystine is by far the least soluble leading to recurrent kidney stones. Type I cystinuria is inherited as an autosomal recessive disorder, while the inheritance of type II is cystinuria is less clear but likely an autosomal dominant disorder with incomplete penetrance [140, 141]. Patients with SLC7A9 mutations may have a milder and later in onset of stone formation and may only develop stones if volume depleted and they consume a high protein diet [140, 142]. Unlike rBAT, B^{0+}AT is predominantly expressed in the early proximal convoluted tubule, although it overlaps with the expression of rBAT [133, 143]. While both rBAT and B^{0+}AT can function as cystine/dibasic amino acid transporters, they likely function in vivo as a heterodimer [144]. rBAT has been shown to be developmentally regulated with no or very low expression in neonatal rats before weaning [145]. There is an increase in rBat expression on the brush border membrane at the time of weaning but to only $<$15% of the adult level [145].

Neonates have a generalized aminoaciduria, which is more pronounced in premature neonates [146–148]. Infants have also been shown to have a higher urine concentration of most amino acids compared to young children [145, 146]. While there have been numerous studies examining amino acid transport using a number of species, most have utilized kidney slices or slurries of renal tubules. These studies are complicated by the fact that one is looking simultaneously at cellular uptake, metabolism of the amino acid, and basolateral exit (often from a collapsed tubule). Examination of glycine transport in tubule suspensions and kidney slices of neonates and adults have provided disparate results. Glycine uptake has been shown to be the same in neonates and adults in some studies [149, 150] and lower in neonates than adults in others [151, 152]. The few studies looking at brush border membrane during development, a more direct way of studying uptake transport across the apical membrane, have shown lower rates of amino acid transport in the neonate compared to the adult [153–155].

Organic Anion and Cation Transport

In addition to filtration and reclamation, the kidney has the ability to secrete some substances through organic anion and cation transporters designated OATs and OCTs. There are multiple organic anion transporters on the basolateral membrane of the proximal tubule with different substrate specificities [156–159]. Organic acids transported by OATs include prostaglandins, uric acid, nonsteroidal anti-inflammatory drugs, β lactam antibiotics, antiviral medications, para-amino hippurate, probenecid, diuretics, salicylates, methotrexate, and many others [157–159]. Many of these substances are protein bound in the blood which limits their excretion by glomerular filtration. Secretion of organic anions is an example of tertiary active transport [158, 159]. For example, organic anions are taken up into the cell predominantly in exchange for α-ketoglutarate which enters the cell via a sodium dicarboxylate cotransporter. The energy for this whole process is the basolateral Na^+,K^+-ATPase. The organic acid transported inside the cell must exit across the apical membrane to enter the urine. The mechanism for this includes members of the multidrug resistance protein family as well as other organic anion secretory exchangers [157–160]. The organic cation excretion is via an organic cation transporter on the basolateral membrane down its electrochemical gradient with secretion into the lumen can be via a number of different mechanisms including in exchange for a proton or via a multidrug resistant protein [160].

Para-amino hippurate is almost totally removed from the blood with one pass through the kidney and can be used as a measure of renal blood flow. Para-amino hippurate is primarily transported across the basolateral membrane of the proximal tubule via OAT1 [161, 162]. Para-amino hippurate has been used to assess the maturation of renal blood flow in humans and to determine the maturational changes in organic anion transport. Studies in humans have shown that there is a maturational increase in para-amino hippurate secretion with adult values being attained at about 2 years of age [163, 164]. Para-amino hippurate secretion is less in premature than term neonates [3].

There are a number of factors that could contribute to the maturational increase in organic anion secretion. Organic anion secretion requires an organic anion transporter, a sodium-dependent organic acid cotransporter, and the Na^+,K^+-ATPase to mediate intracellular transport of the organic acid and an apical secretory mechanism to secrete the organic acid; thus, a paucity in any of these transporters in neonates, compared to adults, could be the rate limiting step. While OAT1, OAT2, OAT3, and OAT5 have been shown to be present in the late gestation fetus, expression of each of these OATs increases during postnatal development [162, 165–168]. There is also a maturational increase in ATP-binding cassette (ABC) transporters, which also are involved in drug secretion [162].

One of the unique features of organic anion transport is that it can be induced prematurely during renal development by an organic anions [169–172]. This is not true of adult animals where organic anions do not cause a stimulation in transport [170]. In vitro microperfusion studies have demonstrated intrinsic increases in the rate of transport with postnatal age in rabbits and that pretreatment with penicillin in vivo increased the rate of para-amino hippurate secretion in isolated proximal straight tubule perfused in vitro [169]. The mechanism of this induction of organic anion transport by organic acids is unclear.

Phosphate Transport

The adult ingests approximately 1–1.5 g of phosphorus per day and of that ~80% is absorbed. The adult must be in neutral phosphorus balance, meaning that the amount of phosphorus absorbed from day to day has to equal that excreted. The phosphorus in our body is predominantly in the form of phosphate. At a pH of 7.4, there is a 4:1 ratio of HPO_4^{-2}/ $H_2PO_4^{-1}$. The kidney maintains phosphate balance by the ability to regulate phosphate transport, which predominantly occurs in the proximal tubule (see also ▶ Chap. 40, “Renal Hypophosphatemia”). The main factors that regulate renal phosphate transport are dietary intake and hormones including parathyroid hormone, FGF-23, and growth hormone. Phosphate is essential for bone growth and 85% of our phosphate is in bones. In addition, phosphate is involved in a myriad of enzymatic reactions and is present in nucleotides, phospholipids, and proteins. Unlike the adult, the neonate must be in positive phosphate balance for growth. This section will review phosphate transport and then discuss developmental changes which occur in transport and its regulation which allow the neonate to be in positive phosphate balance.

The transporters involved in the regulation of phosphate transport are shown in Fig. 7. The first phosphate transporter cloned, designated NaPi-1, did not have the characteristics previously identified in physiologic studies and its function is still not clear [173, 174]. There are two sodium-dependent phosphate transporters on the apical membrane of the proximal tubule, one designated NaPi-IIa [175] and the other NaPi-IIc [176]. NaPi-IIa is an electrogenic transporter that transports three sodium ions with one phosphate (HPO_4^{-2}), while NaPi-IIc transports two sodium ions with every phosphate and is electroneutral [176, 177]. NaPi-IIa and Napi-IIc are regulated by PTH and dietary phosphate intake [178–181]. Phosphate exits the proximal tubule by a transporter which has not yet been identified and characterized. NaPi-IIb is the phosphate transporter on the intestinal apical membrane responsible for absorption of dietary phosphate [182].

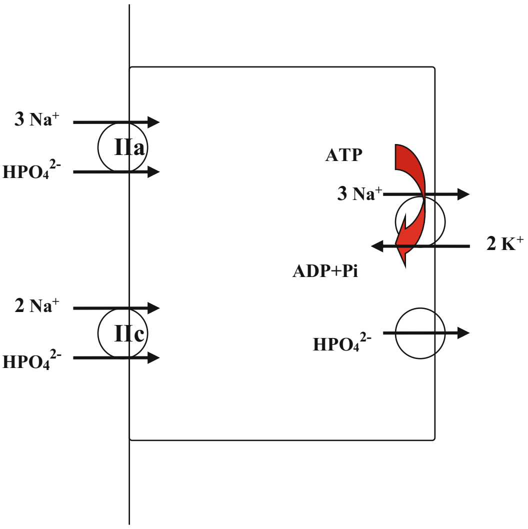

Fig. 7 Diagram of phosphate transport in the proximal tubule. The apical phosphate transporter NaPi-IIa (top) is the predominant phosphate transporter in adult rodents. NaPi-IIc (bottom) is the predominant phosphate transporter on the apical membrane of neonatal rodents. NaPi-IIa is electrogenic while NaPi-IIc is electroneutral. NaPi-IIc is the main phosphate transporter on the apical membrane of the proximal tubule in humans

The serum phosphate levels are higher in neonates than adults [183, 184]. Since the glomerular filtration rate in the neonate is only a fraction that of the adult, a low GFR could theoretically be responsible for the relative hyperphosphatemia in neonates. However, studies in humans found that the fraction of phosphate reabsorbed compared to the glomerular filtration rate was higher in neonates and infants than that in adults [183–186]. In the first 24 h of life, human neonates reabsorb over 95% of the filtered phosphate [183]. This level drops to 90% by about week of age [183, 184]. This fractional reabsorption of phosphate in neonates meets or exceeds the resorptive capacity of adults and older children eating a normal phosphate diet [186].

As seen with humans, young rats have a greater rate of renal phosphate reabsorption of than adult rats [187]. An increase in phosphate transport was also found in rats that received a parathyroidectomy indicating that a blunted response to parathyroid hormone could not explain the higher rates of phosphate transport in neonates compared to adults [187]. Finally, while both young and adult rats responded to a low phosphate diet with an increase in the fractional reabsorption of phosphate, the magnitude of renal phosphate absorption was again higher in young animals [187].

While the above studies are consistent with an enhanced tubular resorptive capacity in neonates, this could be due to a higher resorptive capacity of the neonatal tubule, a diminished response to a phosphaturic factor(s) or the result of an increased response to a substance which increases phosphate transport. To determine if there was an inherent increase in tubular phosphate transport, Johnson and Spitzer examined phosphate absorption in neonatal and adult kidneys perfused in vitro [188]. As shown in Fig. 8, neonatal kidneys had a higher phosphate resorptive rate at any filtered load of phosphate which can only be due to an increased inherent rate of renal phosphate reabsorption. In addition, they found that while addition of parathyroid hormone to the perfusate caused a phosphaturia in adult kidneys, there was no increase in phosphate excretion in neonatal kidneys [188]. These studies directly demonstrate that neonates also have an attenuated response of one of the primary factors regulating phosphate transport, parathyroid hormone. A blunted affect of parathyroid hormone on phosphate reabsorption has also been demonstrated in young rats compared to adult rats in vivo [189, 190].

Micropuncture studies of neonatal and adult guinea pigs and rats have also demonstrated a higher intrinsic rate of proximal tubule phosphate transport in young animals [191, 192]. Studies using brush border membrane vesicles have found that the maximal rate (Vmax) of phosphate transport was several fold higher in neonates than adults, while there was no difference in the Km, the phosphate concentration at half maximal velocity [193]. A low phosphate diet increased the Vmax of the sodium phosphate transporter in adult guinea pigs while a high phosphate diet had the opposite effect. However, there was no significant difference in Vmax for phosphate uptake in brush border membranes from neonates gavaged with a low phosphate diet despite an ~50% decrease in serum phosphate [193]. A high phosphate diet in neonates resulted in a doubling of the

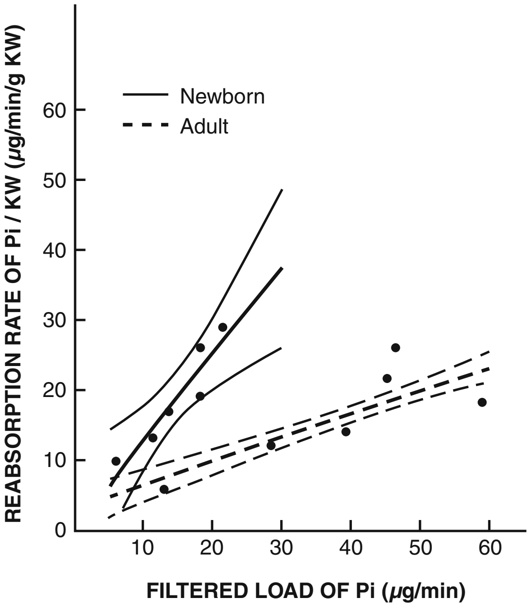

Fig. 8 The rate of phosphate absorption by isolated perfused kidney preparation. As the filtered load increases, there was an increase in the resorptive rate in both the neonate and the adult kidney. At all filtered loads, the rate of phosphate reabsorption per gram of kidney weight was higher in the neonate. (From Ref. [188], with permission)

serum phosphate, while there was little change in serum phosphate in adults. However, brush border membrane vesicles from adults on a high phosphate diet showed a more marked decrease in brush border membrane phosphate transport compared to neonates [193]. Thus while dietary phosphate and serum phosphate levels are important regulators of proximal tubule phosphate transport in adults, phosphate transport is rather fixed in neonatal guinea pigs and not significantly regulated by serum phosphorus levels or dietary phosphate intake. As shown in Fig. 9, 3-week-old rats have a maximal rate of phosphate absorption that was higher than that of adult rats [194]. In young and adult rats, there was an augmentation in the maximal capacity of phosphate reabsorption with a low phosphate diet [194]; however, there was a greater effect of phosphate deprivation on brush border membrane vesicle phosphate uptake and NaP-IIa protein abundance in 4-week-old rats compared to older adult rats [192]. Thus, while there may be a species difference, it appears that the ability to respond appropriately to a low dietary phosphate intake with an appropriate increase in phosphate transport occurs after weaning and is greater in weanling rats than in adults [192]. Finally, the driving force for phosphate entry across the apical membrane may be greater in neonates.

Maturational studies examining the changes in NaPi-IIa expression have revealed that NaPi-IIa mRNA and protein are not detected in developing nephrons until there is a distinct brush border membrane [195]. NaPi-IIa protein abundance was greater in brush border membranes from 13-day-old rats compared to 22-day-old rats [195]. Others, however, have found that brush border membrane vesicles from suckling and adult rats had a slower rate of phosphate uptake than weanling rats (21-day old) [196]. There was no change in NaPi-IIa mRNA abundance, but studies in brush border membrane vesicles revealed that 21-day-old rats had the highest NaPi-IIa protein expression [196]. Studies comparing 28-day-old rats to adult rats have also demonstrated greater brush border membrane NaPi-IIa protein abundance in young rats than adults [192]. The higher rate of renal phosphate transport is likely the major reason for the higher serum phosphate levels in neonates and weanling rats compared to adults. The high rates of phosphate transport in weanling rodents suggested that there may be a different transporter with greater expression during early stages of development [197]. Indeed, NaPi-IIc, another phosphate transporter on the apical membrane of the proximal tubule, has its highest expression rodents at the time of weaning [176]. NaPi-IIc, like NaPi-IIa, is regulated by dietary phosphate uptake and PTH [176, 198]. The relative importance of NaPi-IIa and NaPi-IIc may be quite different in humans. Patients with hereditary hypophosphatemic rickets with hypercalciuria, a rare autosomal recessive characterized by hypophosphatemia secondary to renal phosphate wasting and high vitamin D levels, have a mutation in the gene encoding NaPi-IIc indicating that NaPi-IIc is the predominant renal phosphate transporter in humans and that NaPi-IIa cannot compensate for the loss of NaPi-IIc [199].

Growth hormone increases phosphate transport via stimulation of IGF-1 in the proximal tubule [200]. Brush border membrane vesicle

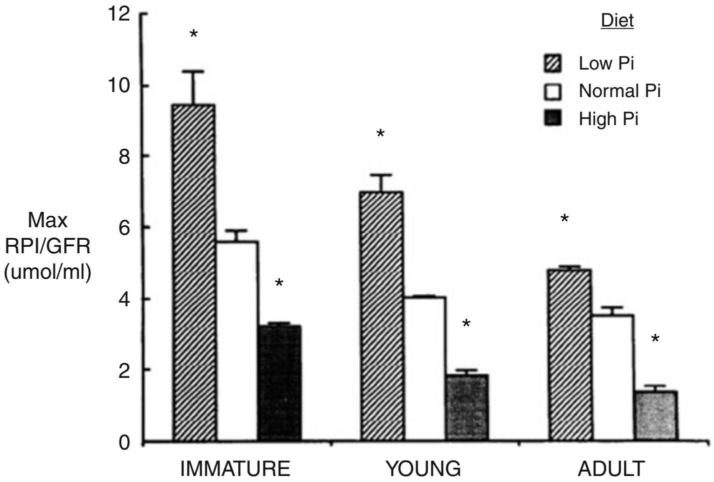

Fig. 9 Age-dependent maximal phosphate reabsorption rats at 3–4 weeks (immature), 6–7 weeks (young), and 12–13 weeks of age (adult). All rats were parathyroidectomized. A low dietary phosphate intake stimulated phosphate absorption in all age groups. The maximal capacity for phosphate absorption is found in the immature groups which need phosphate for growth. (From Ref. [194], with permission)

phosphate transport is increased in dogs that were administered growth hormone compared to vehicle treated controls [201]. While growth hormone is not a significant regulator of phosphate transport in the adult, this may not be the case in the growing animal. Administration of a growth hormone-releasing factor antagonist, which suppresses growth hormone secretion, has no effect on phosphate transport in adult rats, but significantly reduces phosphate absorption in young growing rats [202–204].

There are other hormones that have been shown to regulate phosphate transport including insulin [205], fibroblast growth factor-23 [206–208], frizzled-related protein 4 [209, 210], and Klotho [211, 212]. These hormones may have differential effects on phosphate transport in the neonate and adult, but this is yet to be determined.

Proximal Tubule Acidification

The proximal tubule reabsorbs 80% of the filtered bicarbonate. Luminal proton secretion occurs via the Na^+/H^+ exchanger and the H^+-ATPase. In the adult, one-third of proton secretion is via the luminal H^+-ATPase, and two-thirds is mediated by the luminal Na^+/H^+ exchanger that is designated NHE3 [213, 214]. The secreted proton titrates the filtered HCO_3^- to generate H_2CO_3 which is converted to CO_2 and H_2O by luminal carbonic anhydrase (Carbonic anhydrase IV). CO_2 diffuses into the cell and combines with H_2O which is facilitated by intracellular carbonic anhydrase (Carbonic anhydrase II) to regenerate H_2CO_3. H_2CO_3 dissociates into a proton that can be secreted across the apical membrane, and bicarbonate that exits the basolateral membrane via the basolateral $Na(HCO_3)_3$ symporter. The sodium which enters the call via the Na^+/H^+ exchanger exits the basolateral membrane by the Na^+,K^+-ATPase, which provides the driving force for luminal proton secretion by the Na^+/H^+ exchanger. There are maturational changes in most of these processes that will be described below.

Neonates have a lower serum bicarbonate concentration than adults, which is the result of a lower threshold for bicarbonate [215]. The threshold is the serum level where all of the filtered solute can be reabsorbed. If the concentration in the plasma exceeds the threshold, there will be more filtered solute than can be reabsorbed and the excess will be excreted into the urine until the plasma level is once again at the threshold level (see Fig. 5). Premature neonates can have physiologic bicarbonate concentrations as low as 15 mEq/l [216]. The lower bicarbonate threshold is mediated in large part by the lower rate of proximal tubule acidification. The fine tuning of renal acidification is mediated in the distal nephron which, by and large, is responsible for the secretion of acid from metabolism and new bone formation. Studies have shown that there is a maturational increase in bicarbonate absorption during postnatal development [108, 217], which accounts for the mutational increase in the bicarbonate threshold.

The greatest developmental changes in proximal tubule acidification occur on the apical membrane. There is a fourfold increase in Na$^+$/H$^+$ exchanger activity during postnatal maturation and an even greater increase in apical H$^+$-ATPase activity [213, 218, 219]. Low levels of Na$^+$/H$^+$ exchanger activity have been measured in the fetus as well [220]. While 1–2-week-old neonatal rats have Na$^+$/H$^+$ exchanger activity on the apical membrane, as shown in Fig. 10, virtually no NHE3 exists on the neonatal brush border membrane [219, 221]; in contrast, NHE3 is the primary Na$^+$/H$^+$ exchanger found on the apical membrane of the adult proximal tubule [222, 223].

Surprisingly, NHE3 knockout mice maintain some proximal tubule apical membrane Na$^+$/H$^+$ exchanger activity [224]. The apical Na$^+$/H$^+$ exchanger likely responsible for this non-NHE3 Na$^+$/H$^+$ exchanger activity is NHE8, a neonatal NHE isoform [225, 226]. NHE8 has sodium-dependent proton extrusion capabilities, which made it a potential candidate for the developmental isoform [227]. As shown in Fig. 10, apical NHE8 is predominantly present in neonatal proximal tubules at a time when NHE3 was almost undetectable [221, 228]. Similar to NHE3 in adults [223, 229, 230], NHE8 activity increases with metabolic acidosis [228, 230, 231]. The developmental isoform switch is likely mediated by the increase in thyroid hormone and glucocorticoids that occur at the time of birth through weaning [232, 233].

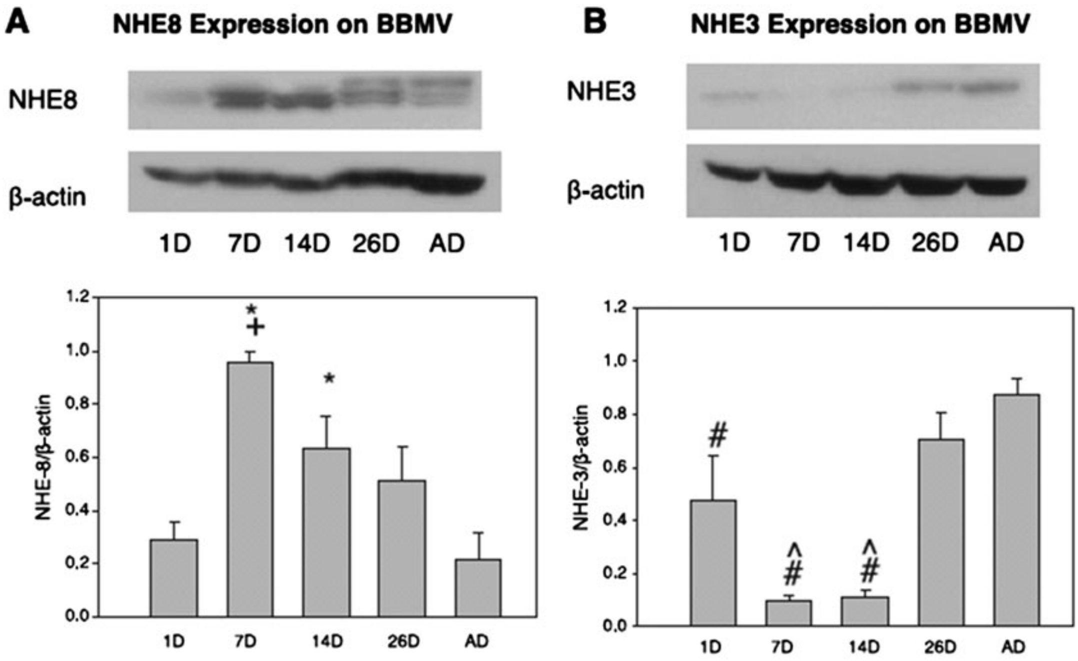

Fig. 10 Immunoblots of rat brush border membrane vesicles depict age-related changes in NHE8 (**a**) and NHE3 (**b**) protein abundance. As is seen, there is higher expression of NHE8 in the neonate than in the adult on brush border membrane vesicles (BBMV). The expression of NHE3 is highest in the adult. The higher NHE3 protein abundance at 1 day of age is likely the result of glucocorticoids at the time of birth. (From Ref. [221], with permission). *D* day, *AD* adult

The $Na(HCO_3)_3$ symporter mediates bicarbonate exit in both the neonatal and adult proximal tubule. While there is a maturational increase in basolateral membrane $Na(HCO_3)_3$ symporter activity, it is relatively small compared to the magnitude of the change in Na^+/H^+ exchanger activity on the apical membrane [234]. In addition to bicarbonate exit, the basolateral membrane $Na(HCO_3)_3$ symporter plays an important role in pH regulation of the proximal tubule cell [234, 235].

Carbonic anhydrase increases the rate of the interconversion of CO_2 and H_2O to H_2CO_3. Carbonic anhydrase II is located intracellularly in proximal and distal tubule acidifying cells and comprises ~95% of cell carbonic anhydrase activity. Carbonic anhydrase IV is on the apical and basolateral membrane of renal acidifying cells and comprises ~5% of carbonic anhydrase activity [236]. Both carbonic anhydrase II and IV increase during maturation of proximal and distal acidification, although neither is likely a limiting factor causing the maturational increase in renal acidification in the proximal or distal tubule [237, 238].

Since the developmental increase in renal acidification is due primarily to apical proton secretion, many studies have examined the cause for the increase in Na^+/H^+ exchanger activity during postnatal development. There is a substantive increase in both thyroid hormone and glucocorticoids at the time of weaning and both hormones increase in parallel with the increase in proximal tubule Na^+/H^+ exchanger activity [81–84]. Administration of either glucocorticoids or thyroid hormone prior to the normal maturational increase in either hormone results in a premature increase in exchanger Na^+/H^+ activity and NHE3 protein abundance [81, 217, 239]. Both thyroid hormone and glucocorticoids increase NHE3 activity by increasing transcription [240, 241]. Glucocorticoids have also recently been shown to increase the insertion of NHE3 into the apical membrane of proximal tubular cells by a posttranscriptional mechanism [242]. Interestingly, neither prevention of the maturational increase in glucocorticoids or thyroid hormone alone can totally prevent the postnatal increase in Na^+/H^+ exchanger activity and NHE3 mRNA and protein abundance [81, 217, 243, 244]. Thus, there appears to be some redundancy in the postnatal maturational triggers for NHE3. As demonstrated in Fig. 11, prevention of the maturational increase in both hormones results in the total prevention of the postnatal increase in NHE3 mRNA, protein abundance and Na^+/H^+ exchanger activity [245]. Both glucocorticoids and thyroid hormone have also been shown to decrease the expression of NHE8 providing further evidence that thyroid hormone and glucocorticoids are the principle factors responsible for the developmental isoform switch that occurs at weaning [232, 233].

Proximal Tubule NaCl Transport

The proximal tubule receives the glomerular ultrafiltrate and changes composition of the tubular fluid in an isosmotic fashion. The early proximal tubule reabsorbs glucose, amino acids, and bicarbonate in preference to chloride [246, 247]. The reabsorption of sodium with glucose and amino acids results in a lumen negative potential difference (due to increased lumenal chloride). The luminal fluid in the late proximal tubule has a higher chloride and lower bicarbonate concentration than that of the peritubular fluid. The lumen to peritubular chloride gradient provides a driving force for the passive diffusion of chloride across the paracellular pathway.

In the early proximal tubule, the transcellular reabsorption of sodium with glucose and amino acids results in a lumen negative potential difference. This lumen negative potential provides a driving force for either chloride absorption or sodium secretion across the paracellular pathway. Whether chloride is absorbed or sodium is secreted is dependent on the relative permeabilities of chloride to sodium in the proximal tubule. The relative chloride to sodium permeability is higher in the adult than the neonate, so passive chloride transport secondary to the lumen negative potential difference in the early proximal tubule does not occur to a significant degree in the neonate [48, 248]. The luminal chloride gradient in the late proximal tubule results in a driving force for chloride diffusion across the paracellular pathway [48, 248]. The diffusion of

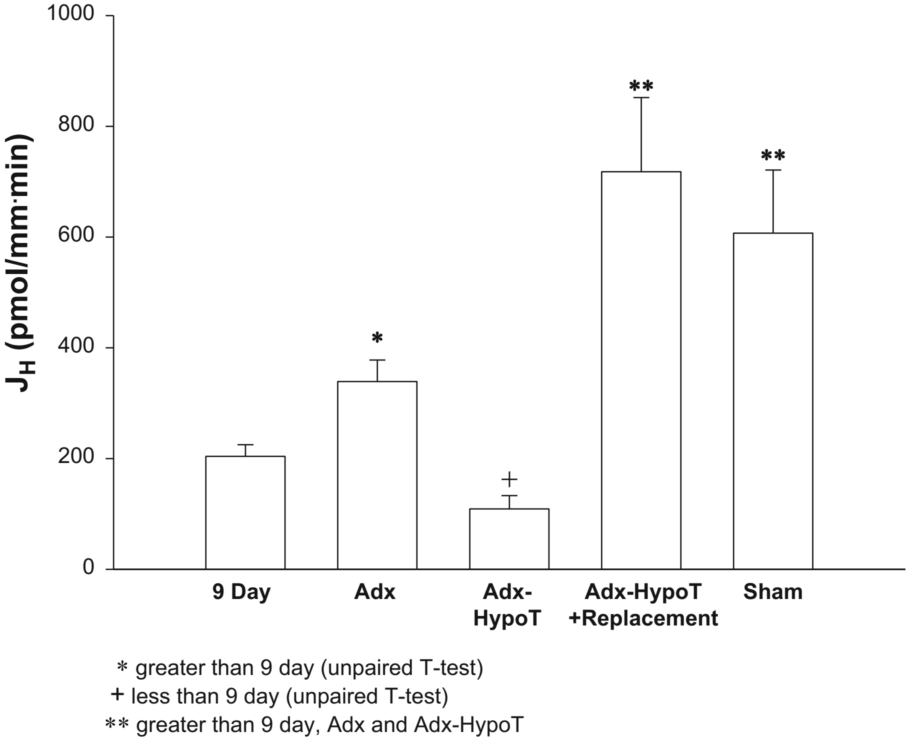

Fig. 11 Apical Na$^+$/H$^+$ exchanger activity in perfused rat tubules. These include 9-day-old rats, and adults that were adrenalectomized as neonates (Adx), adults that were adrenalectomized and hypothyroid (HypoT) since the neonatal period, adults that were adrenalectomized and hypothyroid since the neonatal period but given thyroid and glucocorticoid replacement before study and sham controls. The 9-day-old rats had a lower rate of Na$^+$/H$^+$ exchanger activity than the sham adult. Neonatal adrenalectomy did not totally prevent the maturational increase in Na$^+$/H$^+$ exchanger activity, but the maturational increase in Na$^+$/H$^+$ exchanger activity was abrogated in the adrenalectomized hypothyroid group. (From Ref. [245], with permission)

chloride across the paracellular pathway results in a lumen positive potential difference, and a driving force for the paracellular transport of sodium.

In the adult proximal tubule, approximately half of sodium chloride transport is active and transcellular, and half is passive and paracellular [244, 249, 250]. Active chloride transport is mediated by parallel action of the Na$^+$/H$^+$ and Cl$^-$/base exchangers on the apical membrane [244, 251–253]. It is still somewhat unclear which base is exchanged for chloride as there is evidence for chloride exchange for hydroxyl, formate, and oxalate ions [244, 254–258]. The rate of active transcellular chloride transport is lower in the neonate than that in adults. This is due to the lower rate of the apical Cl$^-$/base exchanger [244, 259] and the Na$^+$/H$^+$ exchanger discussed above [213, 218, 219]. The driving force for active transcellular NaCl transport is the basolateral Na$^+$,K$^+$-ATPase that has lower activity in the neonatal proximal tubule [73, 74, 260]. There are a number of factors that regulate proximal tubule NaCl transport including renal nerves, dopamine, and angiotensin II. The serum levels of most hormones that regulate sodium absorption in the neonate are equal to or higher than in the adult, although in general neonates have a blunted response to most regulatory hormones.

There are also changes in the properties of the paracellular pathway during postnatal development [48, 248, 261, 262]. Most importantly, the permeability of the proximal tubule to chloride ions is lower in the neonate than the adult [48, 248, 262]. The low permeability to chloride ions results in almost no passive paracellular chloride transport in the neonate [48, 248]. As discussed, the permeability properties of an epithelium are determined by the expression of a family of proteins called claudins. The claudin proteins in the tight junction change during the postnatal development. Claudins 6, 9, and 13 are present in the neonatal proximal tubule but not in the adult [261]. Claudin 6 and 9 decrease the chloride permeability of the proximal tubule and increase the paracellular resistance [263].

Of the potential secreted factors that cause the maturational changes in paracellular chloride transport, only thyroid hormone has been examined [264]. Administration of thyroid hormone prior to the normal maturational increase results in an increase in chloride permeability [264]. In contrast, maintaining a hypothyroid state into adulthood prevents the maturational increase in chloride permeability. It is as yet to be determined if thyroid hormone is the endogenous factor that causes the proximal tubule claudin isoform changes during postnatal development.

Proximal Tubule Water Transport

The proximal tubule reabsorbs most of the glomerular filtrate without a significant change in the luminal osmolality. For this to occur, the proximal tubule must be very permeable to water. Proximal tubule water movement occurs both across the cell and paracellular pathway [265–267]. The constitutively water permeable proximal tubule and thin descending limb have water channels on the apical and basolateral membranes [36]. The isoform of this water channel present in the proximal tubule is aquaporin 1 [268–271]. Direct evidence of transcellular water transport comes from aquaporin 1 knockout mice, which have a marked decrease in proximal tubule sodium and water absorption [265, 272]. There is a paucity of water channels in the fetal kidney and an increase in expression of aquaporin 1 does not occur until birth [273, 274]. Deletion of claudin 2, a protein in the tight junction of the proximal tubule decreases proximal tubule transport by 25%, consistent with some water reabsorption via the paracellular pathway [265].

Direct measurements of water permeability have demonstrated that the neonatal rabbit proximal tubule has a higher water permeability that that of the adult [275]. To determine the mechanism for the higher water permeability in neonatal rabbit tubules, studies were performed examining the water permeability of apical and basolateral membrane vesicles [276–278]. Despite the higher transepithelial water permeability, the water permeability of the apical and basolateral membrane were lower in the neonate than the adult and as expected there was less aquaporin 1 expression on both the apical and basolateral membranes of the proximal tubule of the neonate [277, 278]. The apparent paradox between the higher water permeability in the neonatal proximal tubule and the lower water permeability of the apical and basolateral membranes was resolved with measurements of the contribution of the intracellular compartment to water movement in the neonatal and adult proximal tubule. The intracellular compartment was found to cause a large resistance to water flow in adult tubules, but neonatal proximal tubule intracellular compartment was less of a constraint to transcellular water movement [266].

The postnatal increase in glucocorticoids levels is a likely factor in mediating the above maturational changes in water permeability and aquaporin 1 expression. Administration of glucocorticoids to neonatal rabbits resulted in an increase in brush border membrane water permeability and aquaporin 1 expression [279]. Conversely, the developmental increase in thyroid hormone was shown not to affect postnatal maturational changes in water transport [280].

Thick Ascending Limb

The thick ascending limb is responsible for the reabsorption of 30% of filtered NaCl. Mutations in the transporters on the apical and basolateral membrane responsible for transport in this segment result in Bartter Syndrome (see ▶ Chap. 41, “Inherited Disorders of Sodium and Potassium Handling”). The thick ascending limb and the distal convoluted tubule are impermeable to water and the reabsorption of NaCl without water generates a luminal fluid with an osmolality of ~50 mOsm,Kg water. In the absence of ADH action on the collecting tubule, this dilute urine will be excreted. The medullary interstitial hypertonicity is largely generated by active NaCl reabsorption without water by the medullary thick ascending limb.

Reabsorption of NaCl is due to secondary active transport with the basolateral Na^+,K^+-ATPase generating a low intracellular sodium to provide a driving force for luminal sodium entry (see Fig. 12). Sodium enters the cell vial the loop diuretic sensitive $Na^+/K^+/2Cl^-$ cotransporter [281, 282]. The $Na^+/K^+/2Cl^-$ cotransporter is electroneutral yet there is a lumen positive transepithelial potential difference in the thick ascending limb [283]. The positive luminal potential is generated by apical potassium recycling via the potassium channel, ROMK1 [284, 285]. With recycling of potassium back into the lumen, there is the net reabsorption of one sodium and two chloride ions which exit the cell across the basolateral membrane. Sodium exits the cell via the basolateral Na^+,K^+-ATPase. Chloride predominantly exits the cell via a chloride channel designated ClC-Kb [286–288]. A subunit of this chloride channel designated barttin is important in the function of ClC-Kb [289]. The lumen positive potential difference, generated by potassium secretion into the lumen, generates a driving force for the passive paracellular reabsorption of cations including Mg^{++} and Ca^{++} [290–294]. The unique permeability properties of the thick ascending limb are due to the expression of claudin 16 and claudin 19 which interact synergistically to increase cation permeability across the paracellular pathway [295]. Elimination of either claudin 16 or claudin 19 affects the expression of the other protein in the tight junction and decreases cation permeability [295, 296]. Claudin 16 or claudin 19 are mutated in familial hypomagnesemia with hypercalciuria and nephrocalcinosis where there is renal magnesium and calcium wasting [295, 297]. Claudin 19 is also present in the eye and patients with claudin 19 mutations also have vision problems [298, 299].

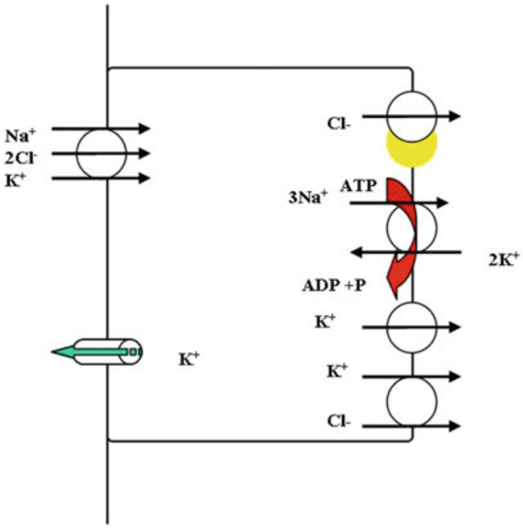

Fig. 12 Diagram of a thick ascending limb cell. On the apical membrane is the $Na^+,K^+/2Cl^-$ cotransporter that is sensitive to loop diuretics and the potassium channel designated ROMK (renal outer medullary potassium channel) that is depicted as the green arrow. The basolateral membrane has a Na^+,K^+-ATPase, a KCl cotransporter, a chloride channel designated ClC-Kb, with its accessory channel designated barttin in yellow and a potassium channel. A loss of function mutation in the $Na^+K^+/2Cl^-$ cotransporter, ROMK, ClC-Kb, or barttin results in Bartter's syndrome

Mutations of the $Na^+/K^+/2Cl^-$ cotransporter [300], ROMK [301, 302], ClC-Kb [303], and barttin [289, 304] all cause Bartter syndrome. Barttin is also expressed in the ear where it is a subunit of ClC-Ka and ClC-Kb. Mutations in barttin cause sensory neural hearing loss [289, 304]. A fifth type of Bartter syndrome is due to an activating mutation of the calcium-sensing receptor [305, 306]. Patients with this latter autosomal dominant disorder have hypocalcemia due to activation of the calcium-sensing receptor in the parathyroid glands. In addition, the calcium-sensing receptor is expressed on the basolateral membrane of the thick ascending limb and activation of the receptor results in inhibition of both $Na^+/K^+/2Cl^-$ cotransporter and ROMK [305].

Micropuncture studies examining fluid from the early distal tubule found that the osmolality of the fluid was significantly lower in the adult than the neonatal rat [307]. This is consistent with lower rates of sodium transport in the neonatal thick ascending limb, although this study did not examine the latter parts of the diluting segment. Sodium transport in the thick ascending limb has been directly examined in vitro and shown to be fivefold lower in the neonate than in the adult [308]. Human neonates are able to dilute their urine to a comparable level as an adult (~50 mOsm,Kg water). This is vital since neonates ingest mother's milk, which is a hypotonic fluid. The ability of a neonate to dilute urine to the same extent in spite of a lower rate of sodium transport as an adult is due a lower glomerular filtration rate and delivery of sodium chloride to this segment in the neonate.

The $Na^+/K^+/2Cl^-$ cotransporter can first be detected in the mid-late gestation rat thick ascending limb and macula densa [309]. Rats have a postnatal maturational increase in $Na^+/K^+/2Cl^-$ cotransporter, ROMK, Na^+,K^+-ATPase mRNA and protein abundance but no change in ClC-K mRNA abundance [310]. Administration of dexamethasone before the normal maturational increase at the time of weaning resulted in a premature increase in urinary concentrating ability and increase in $Na^+,K^+/2Cl^-$ cotransporter, Na^+,K^+-ATPase mRNA and protein abundance, but no change in ROMK protein abundance [310]. There is also a postnatal maturational increase in thick ascending limb Na^+,K^+-ATPase activity [74, 311]. The maturational increase in thick ascending limb Na^+,K^+-ATPase activity is accelerated precociously by glucocorticoids and prevented by neonatal adrenalectomy [311, 312].

Distal Convoluted Tubule

The distal convoluted tubule reabsorbs approximately 5% of the filtered sodium. This segment is water impermeable and further reabsorption of salt without water occurs in this segment resulting in the nadir of luminal fluid osmolality. The transporters responsible for NaCl transport in the distal convoluted tubule are shown in Fig. 13. Sodium enters the cell via the thiazide-sensitive cotransporter [313–316]. Mutations in the thiazide-sensitive cotransporter cause Gitelman's syndrome [317–319] (see ▶ Chap. 41, "Inherited Disorders of Sodium and Potassium Handling"). There is also evidence for parallel Na^+/H^+ and Cl^-/base exchange mediating sodium entry in the rat distal convoluted tubule [320]. NHE2 is the isoform of this Na^+/H^+ exchanger [321]. Chloride exits the cell via a basolateral chloride channel ClC-K [322] and a KCl cotransporter KCNQ1 [323, 324]. There is also a basolateral potassium channel [325]. While active transcellular calcium and magnesium transport occurs in the distal convoluted tubule, there is no information about the postnatal developmental expression of these transporters [326, 327].

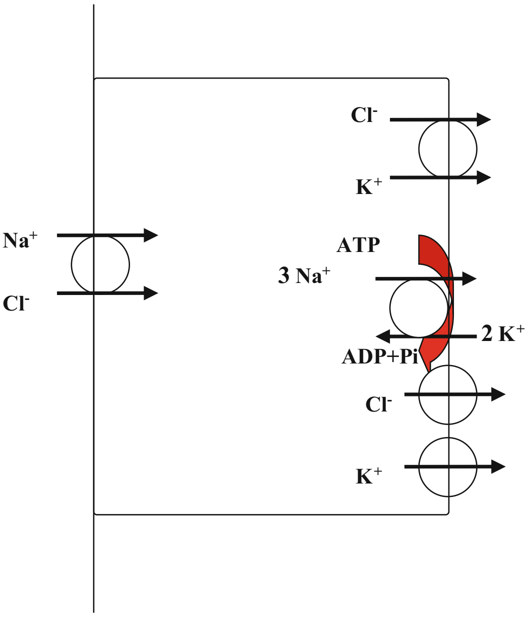

Fig. 13 Distal convoluted cell showing the transporters involved in active sodium reabsorption. The apical NaCl transporter is the thiazide-sensitive cotransporter. Inactivating mutations in the thiazide-sensitive cotransporter lead to Gitelman's syndrome

The distal convoluted tubule is very difficult to study in vitro and in vivo. No studies have been performed to date examining the relative abundance of the thiazide-sensitive cotransporter in the neonate and adult. One study suggests that there is increased sodium absorption in 24-day-old compared to 40-day-old rats [328]. That said, many studies have shown that the neonate is less able to excrete a sodium load compared to the adult [328–330]. For example, administration of isotonic saline equal to 10% of an adult dog's weight resulted in excretion of 50% of the salt load over 8 h, while a similar infusion in a 1–2-week-old dog led to only 10% of the salt load being excreted [328]. This limited ability to excrete a sodium load in the neonatal dog was not due to the lower glomerular filtration rate [328]. Since neonatal sodium transport is reduced in the proximal tubule, thick ascending limb, and collecting tubule, the nephron segment where there was avid neonatal sodium reabsorption was unclear. It is possible that the volume of distribution of the saline infusion was greater in the neonate than the adult, which may account for these findings.

A micropuncture study suggested that the sodium retention in the neonate was the result of avid sodium reabsorption in the distal convoluted tubule [331]. The tubular fluid to plasma Na/inulin (a volume marker) was greater in the early distal tubule in the 24-day-old neonatal rat compared to a 40-day-old rat due to decreased proximal and loop sodium absorption in the younger rat. This difference disappeared in the late distal tubule indicating that the 24-day-old rat had a higher rate of sodium absorption in that distal convoluted tubule. While volume expansion resulted in a higher distal delivery of sodium from the early proximal tubule of the 24-day-old rat, there was less sodium remaining by the end of the distal nephron; this is consistent with the distal convoluted tubule being the segment responsible for decreased ability of neonates failure to excrete a sodium load versus adults.

Urinary Concentration and Dilution

The urine exiting the distal convoluted tubule and entering the collecting duct has an osmolality of ~50 mOsm/Kg water. Whether the urine will be of this osmolality or maximally concentrated will depend on the presence or absence of vasopressin (ADH). Neonates can dilute their urine to nearly the adult level of nearly 50 mOsm/Kg water [332–334]. Thus the neonate which imbibes mother's milk must excrete high amounts of free water [333–335]. However, unlike the normal adult, where it is almost impossible to drink enough water to cause hyponatremia (30 l/day), neonates have a rather limited ability to generate and excrete free water and improperly mixed dilute formula can result in hyponatremia [334].

The maximum urine osmolality of the human neonate is ~400–600 mOsm/Kg water [336–338]. The adult urine osmolality can be achieved at 1.5–2 years of age [337]. There are many potential developmental factors that could limit the ability of the neonate to generate maximally concentrated urine. The factors involved in urine concentration include:

1. The ability to sense an increase in serum osmolality or decrease in extracellular volume and secrete vasopressin
2. Presence of vasopressin receptors on the basolateral membrane of the collecting duct
3. Ability of the collecting duct to generate cAMP
4. Ability of the loop of Henle to generate a concentrated interstitium
5. Presence of medullary architecture to allow maximal concentrating ability
6. Presence of aquaporins on the apical and basolateral membrane of collecting tubules for the transcellar passage of water

During prenatal and postnatal maturation, there are anatomical changes which occur that likely affect urinary concentrating ability. There is an increase in the medullary capillary density, a decrease in medullary interstitial connective tissue, and an increased presence and length of the thin limbs; also the tubules become more tightly packed with cells in the loop decreasing in height with maturation [339, 340]. The length of the papilla increases linearly from day 10 to day 40 in the rat [341]. All these developmental anatomical changes are necessary for the countercurrent multiplication system to be maximally efficient. Accompanied by these anatomical changes are concomitant increases in the medullary sodium and urea concentration [341, 342]. Administration of a high protein diet or urea to human neonates increases the neonates concentrating ability [343, 344]. Thus, part of the limited concentrating ability is the result of the protein content of the diet. Adrenalectomy in neonatal rats prevented the maturational increase in urine osmolality while administration of glucocorticoids prior to the maturational increase in serum glucocorticoid levels results in a premature increase in urinary concentrating ability [341].

Principal cells in the collecting tubule and the cells in the medullary collecting duct express aquaporin 2 on the apical membrane and aquaporins 3 and 4 on the basolateral membrane [345–349]. Aquaporin 3 null mice have diabetes insipidus whereas aquaporin 4 null mice only have a small concentrating defect after water deprivation indicating that basolateral water movement is primarily via aquaporin 3 [350, 351]. Vasopressin causes the intracellular vesicles containing aquaporin 2 to fuse with the apical membrane resulting in the insertion of aquaporin 2 into the apical membrane [346]. There is a developmental increase in aquaporin 2 expression [347, 348, 352]. The maturational increase in aquaporin 2 is accelerated by administration of synthetic glucocorticoids prior to the normal postnatal increase in plasma glucocorticoids [352]. Neither aquaporin 3 nor aquaporin 4 impair urinary concentration in the neonate [347, 353].

The fetus and neonate respond to increases in serum osmolality, stress, and hypovolemia with appropriate increases in plasma vasopressin levels. The fetal sheep has an increase in plasma vasopressin with an infusion of hypertonic saline and increase in plasma osmolality [354–356]. Plasma vasopressin levels also increase in fetal sheep in response to volume depletion induced by hemorrhage or diuretics [356–358] Despite the increases in fetal sheep serum vasopressin levels with stress, infusion of vasopressin in non-stressed fetal sheep resulted in a blunted increase in urine osmolality compared to adult sheep [359]. While it is hard to assess these issues in humans, comparison between a relatively stressful vaginal delivery to a cesarean section has consistently demonstrated higher vasopressin levels in neonates born vaginally [360–363]. There was no correlation with vasopressin levels and the degree of perinatal asphyxia in one study [360], while there was a correlation in another [362]. In sum, it appears that the fetus and neonate can respond to appropriate stimuli with vasopressin secretion, but may have a blunted response to vasopressin.

There is a developmental increase in vasopressin receptors in the kidney; however, vasopressin receptor abundance does not appear to be a limiting factor in urinary concentration in the neonate [364]. Exogenous administration of vasopressin increases the urine osmolality in fetal sheep showing that vasopressin action on the collecting tubule is a prenatal event [359]. Vasopressin acts in the collecting tubule by increasing cAMP. There is some discrepancy about the extent of cAMP production during postnatal maturation in comparison to adults. The sum of the data support that while vasopressin stimulates cAMP production in the neonate, the amount of cAMP generated is attenuated compared to the adult [364–367].

The response of the collecting tubule to vasopressin has been examined in vitro [368–370]. The increase in water permeability in neonatal collecting ducts in response to vasopressin is less than in the adult tubule [368–371]. Studies have shown that the phosphodiesterase activity is greater in the neonatal collecting tubule than the adult [370]. Inhibition of phosphodiesterase activity in neonatal collecting tubules results in comparable water permeability to that of adult tubules demonstrating that enhanced degradation of cAMP in the neonatal collecting tubule likely limits the vasopressin induced increase in water permeability [370]. Vasopressin also increases prostaglandin production in the collecting tubule which in turn attenuates the vasopressin mediated increase in cAMP production [372, 373]. Vasopressin-mediated cAMP production, while less in the neonatal collecting tubule, increases to adult levels in the presence of indomethacin, a prostaglandin synthesis inhibitor [372]. Thus, prostaglandin production by the collecting tubule attenuates the effect of vasopressin in the neonatal tubule to a greater extent than the adult tubule [372].

Distal Tubule Acidification

The distal nephron makes the final adjustment in distal acidification. The distal nephron, under normal circumstances secretes the protons equal to that generated from metabolism and in growing children, the protons liberated from the formation of bone as well. The cortical collecting tubule has two types of cells that are involved in renal acidification. The α-intercalated cell is responsible for proton secretion and is shown in Fig. 14. There is also a β-intercalated cell (see Fig. 14), which can secrete bicarbonate when the animal is alkalotic or eats a diet with a high alkali content [374]. This is atypical for most humans, but not for some mammals which can ingest an alkali diet [375]. The β-intercalated cell has the reverse polarity as the α-intercalated cell but the Cl^-/HCO_3^- exchanger on the apical membrane of the β-intercalated cell is different than that on the apical membrane of the α-intercalated cell.

The neonatal cortical collecting tubule has fewer and less differentiated intercalated cells than that of the adult segment [376, 377]. The rates of both bicarbonate secretion and luminal

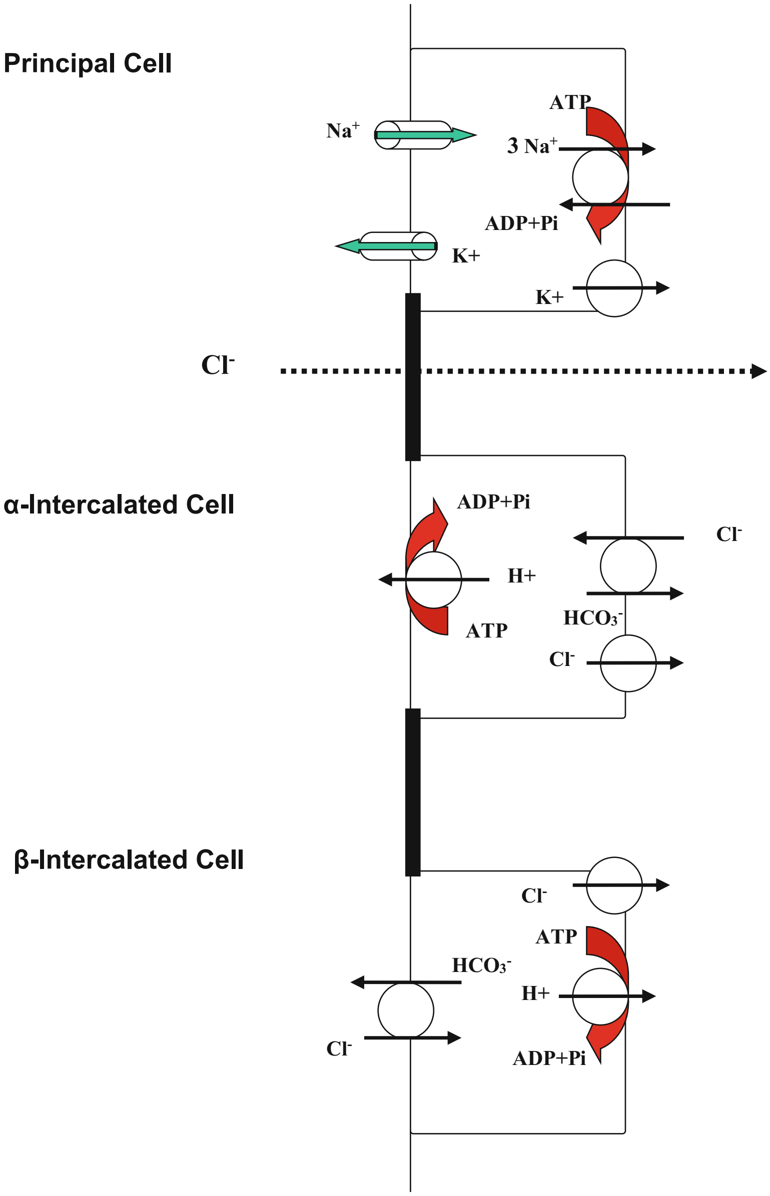

Fig. 14 Three cells of the cortical collecting tubule are demonstrated. The principal cell (top) is shown with sodium entering the cell down its electrochemical gradient via a channel designated ENaC. This generates a lumen negative transepithelial potential difference. Potassium is secreted into the lumen down its electrochemical gradient via ROMK. Chloride moves through the paracellular pathway down the electrical gradient generated by the lumen negative potential difference. The alpha-intercalated cell (middle) secretes protons into the cell lumen via a H^+-ATPase. The bicarbonate generated in this process is secreted across the basolateral membrane via a Cl^-/HCO_3^- exchanger. The beta intercalated cell (bottom) secretes bicarbonate ions in the face of metabolic alkalosis. This cell has the reverse polarity of an alpha-intercalated cell but the Cl^-/HCO_3^- exchanger is different isoform

acidification are reduced in the neonate than in the adult [375, 377, 378]. The intercalated cells in the neonatal inner medullary collecting duct are much more differentiated in appearance than in earlier tubular segments and secrete protons at a rate comparable to the adult [375, 378]. The collecting tubule also has a luminal H^+-K^+ ATPase that secretes protons and reabsorbs potassium from the luminal fluid. It is activated under states of metabolic acidosis and hypokalemia [379]. The H^+-K^+ ATPase can function at comparable rates in the neonatal cortical collecting tubule as that of the adult [380].

Cortical Collecting Tubule Sodium Transport

While relatively little sodium is reabsorbed by the cortical collecting tubule compared to the more proximal nephron segments, it is the final nephron segment responsible for regulating sodium absorption and thus is vitally important for the regulation of sodium homeostasis. Sodium absorption occurs in the principal cell of the collecting tubule, which is shown in Fig. 14. Sodium transport occurs through the epithelial sodium channel designated ENaC which has three subunits. The driving force for sodium entry across ENaC is the low intracellular sodium concentration and the potential difference across the luminal membrane generated by the basolateral Na^+,K^+-ATPase. The Na^+,K^+-ATPase undergoes a maturational increase in this segment, but is not the limiting factor the decrease in neonatal sodium absorption [74]. Trafficking of ENaC to the apical membrane is regulated by aldosterone and vasopressin [381, 382]. Compared to the adult, aldosterone has a blunted effect in the neonate despite the fact that there are higher serum potassium levels in the neonate than adults, and ample aldosterone receptors in neonates [383–389].

Sodium transport in the cortical collecting tubule increases with postnatal development [388, 390]. This increase in sodium transport is paralleled by an increase in the apical expression of ENaC, which is the limiting factor in sodium absorption in this segment [391]. ENaC is composed of a-, ß-, and γ- subunits, and there are developmental increases in mRNA and protein abundance of each during postnatal maturation [391–395]. However, the increase in mRNA abundance occurs shortly after birth in the rat while the increase in protein abundance occurs latter, consistent with posttranscriptional regulation of the ENaC subunits during postnatal development [393]. The limitation to sodium transport via ENaC is not only due to the limited apical expression, but also due to the fact that the transporters on the neonatal apical membrane have a greater probability of being closed rather than open to let sodium into the cell compared to adult transporters [391].

Potassium Transport

Neonates have higher serum potassium levels than adults. Potassium is the predominant intracellular cation and neonates must be in positive potassium balance for growth unlike adults, which excrete the quantity of potassium absorbed from their diet into their urine [379]. Adult animals are more readily able to excrete an exogenous potassium load than is a neonate [396]. Approximately half of the filtered potassium is reabsorbed in the proximal tubule of the adult and neonate by passive diffusion across the paracellular pathway [397]. The loop of Henle reabsorbs the remaining 80% of the delivered potassium in the adult, but only 45% of the delivered potassium in the neonate [397]. Thus, the adult delivers approximately 10% of the filtered potassium to the distal nephron while the neonate delivers 25%. The distal convoluted tubule, connecting tubule, and cortical collecting duct are the sites of potassium secretion and final modulators of urine potassium excretion.

Potassium secretion by a principal cell is depicted in Fig. 14. Sodium enters the principal cell through the apical sodium channel down the favorable electrochemical gradient generated by the Na^+,K^+-ATPase on the basolateral membrane. This results in a lumen negative potential difference and a favorable electrochemical gradient for potassium secretion. While there is a maturational increase in the sodium channel and the Na^+,K^+-ATPase, these are not the limiting factors for potassium secretion. There are two potassium channels on the apical surface of the principal cells of collecting tubule: a channel designated ROMK, and a channel designated the maxi-K channel (also known as the BK channel) that is a flow-dependent channel and activated by stretch [379]. There is a maturational increase in potassium secretion in cortical collecting tubules which was demonstrated by in vitro tubule perfusion [390]. Secretion of potassium by principal cells is paralleled by the maturational increase in potassium channels (ROMK) on the apical membrane of the principal cell [395, 398]. The number of ROMK channels increases during development, but the open probability remains constant [398]. There is also a developmental increase in the flow regulated maxi-K channels [399]. Potassium secretion is regulated by aldosterone and there is resistance to the action of aldosterone despite higher serum levels in the neonate [383–389].

Abstract

Congenital kidney anomalies are the result of embryonic maldevelopment that dates back to the fifth gestational week in humans. At this time-point, the metanephric mesenchyme, which originates from the nephrogenic cord, and the outgrowing ureteric bud, which originates from the nephric duct, display highly coordinated spatiotemporal interactions that result in the development of the kidney and the adjacent urinary tract (see ▶ Chap. 1, "Pre-natal Development of the Kidneys and Urinary Tract"). Disturbances in the molecular communication between the metanephric mesenchyme and the ureteric bud give rise to a spectrum of kidney abnormalities that differ from one another depending on the timing and/or location of the disturbance. Based on the location of the disturbance, congenital kidney anomalies can arise as unilateral or bilateral defects, or they can result in the formation of ectopic kidney tissue. Early perturbations lead to the complete absence of kidney tissue, whereas later events may result in an underdeveloped kidney that is hypoplastic or dysplastic or in a kidney with reduced nephron number. Many of these spatiotemporal disturbances are caused by genetic, epigenetic and/or environmental factors that are also involved in the development of other organs. Therefore, congenital kidney defects may present in conjunction with extrarenal defects or be part of a well-defined clinical syndrome.

In this chapter, we discuss the phenotypic spectrum of human congenital kidney defects that encompasses unilateral renal agenesis (URA), bilateral renal agenesis, renal hypoplasia, renal dysplasia, multicystic dysplastic kidney (MCDK) as well as ectopic kidney tissue, kidney fusion defects (such as crossed fused ectopia and horseshoe kidney), and finally, duplication of the kidney. The clinical presentation, their management, and the syndromes that are associated with congenital kidney anomalies will be discussed. Finally, we provide a state-of-the-art overview of the molecular mechanisms that give rise to congenital kidney anomalies.

Clinical Presentation of Congenital Anomalies of the Kidneys

Antenatal Presentation of CAKUT

Using transvaginal ultrasound, urine first appears in the human bladder at the ninth week of gestation. However, the onset of urine flow and its contribution to amniotic fluid volume is not easily detected by transabdominal ultrasonography until 16 weeks or more. Thus, most disturbances of embryonic renal patterning that lead to congenital anomalies of the kidney and urinary tract (CAKUT) are usually identified at the 20–22-week ultrasound, now widely performed as part of routine antenatal care. Key findings range from sequelae of urinary tract obstruction to monogenic disorders that disturb kidney position to disturbances of cellular patterning in renal glomeruli or tubules. Subsequent ultrasound tests or more refined imaging techniques (i.e., magnetic resonance imaging) later in pregnancy allow physicians to track the evolution of these renal anomalies.

Renal Agenesis

Bilateral renal agenesis (BRA) occurs in about 1: 10,000 live births. Lack of kidney-derived amniotic fluid causes a characteristic pattern of facial compression, limb contractures, amnion nodosum, and pulmonary hypoplasia (Potter syndrome) that limits postnatal viability (Fig. 1). By compromising fetal respiratory movements that optimize fetal lung development, severe oligohydramnios may limit gas exchange and result in an urgent need for intubation and intensive respiratory support after birth.

In most cases, the cause of BRA is not known. However, reports of the absence of renal arteries and ureters in the second trimester suggest arrest of kidney development at an early stage. Roodhooft et al. examined 40 siblings of 41 index cases with BRA and found that 10% had unilateral RA (URA), suggesting a heritable cause [1]. In an Australian cohort, URA was found in siblings of babies with isolated BRA but not in siblings of cases of BRA with multiple malformations [2]. BRA has been associated with recessive mutations in the gene *integrin alpha 8* (*ITGA8*) that encodes a transmembrane receptor important for cell adhesion and cell signaling between the metanephric mesenchyme and ureteric bud [3]. BRA has also been associated with recessive mutations in *fibroblast growth factor 20* (*FGF20*) that is expressed by nephron progenitor cells during kidney development [4], X-linked Kallmann syndrome due to mutations in the *KAL-1* gene, an extracellular matrix protein expressed in the kidney [5], and rarely with heterozygous mutations in the gene encoding the receptor tyrosine kinase *RET* that is expressed in the ureteric bud [6].

Unilateral renal agenesis occurs in about 1:2,000 live births (Fig. 2). The incidence of URA in males (63%) is slightly higher than in females, and the left kidney is more often absent (63%) than the right [7]. Westland et al. reviewed 2,684 patients with URA from many pediatric and adult cohorts and found that about one third had various urinary tract anomalies, including vesicoureteral reflux (24%), ureteropelvic junction obstruction (6%),

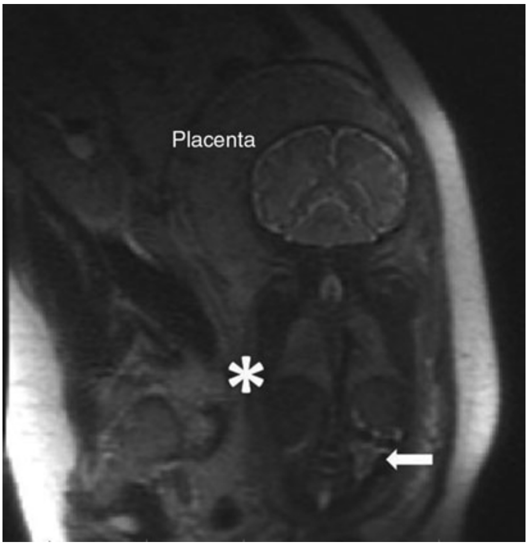

Fig. 1 Magnetic resonance image showing case of Fraser syndrome with the absence of the right kidney, hypoplastic left kidney (*arrow*), and anhydramnios (*asterisk*)

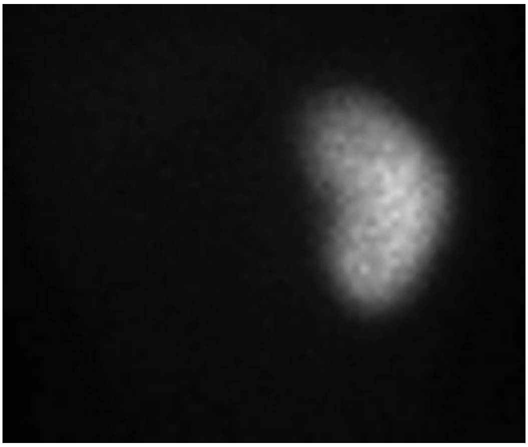

Fig. 2 DMSA scan showing agenesis of the left kidney

megaureter (7%), ureterocoele (1%), and posterior urethral vales (1%) [8]. One third of cases were associated with syndromic extrarenal anomalies. From analysis of a subset of the cohorts, it was determined that the mean GFR was 100 ml/min/ 1.73 m^2 and that the majority of patients with an isolated solitary functioning kidney have stable renal function for many decades. However, 21% had microalbuminuria, 16% had hypertension, and 10% had a glomerular filtration rate <60 ml/min/ 1.73 m^2. It is unclear whether this renal dysfunction is the consequence of a congenital nephron deficit with or without dysplasia in the remaining kidney. In a pediatric cohort of URA/MCDK (multicystic dysplastic kidney) patients from the Netherlands [9], hypertension was seen in 31%, and microalbuminuria was present in 23%, indicating that these issues are generally evident before the age of 18 years.

URA reduces total nephron mass and usually induces compensatory renal hypertrophy in the remaining kidney during fetal life. In an ultrasonographic study of a mixed URA/MCDK cohort, the length of the single functioning kidney was estimated to be 23% longer than normal from the 20th week of gestation onward [10]. Cho et al. proposed that the ratio of the anterior-posterior to transverse diameter of the kidney discriminates appropriately hypertrophied kidneys (1.0) from the ratio in babies with two normal kidneys (0.8) [11].

Unilateral multicystic, dysplastic kidneys may mimic URA when they have involuted prior to evaluation. The MCDK is actually a form of severe renal dysplasia in which the kidney is occupied by tense non-communicating macrocysts [12]; typically, there is little or no functional parenchyma (Fig. 3a, b, c). The renal pelvis and calyces cannot be identified, and the ureteropelvic junction and ureter are usually atretic; ipsilateral vesicoureteral reflux is rare. The incidence of MCDK ranges from 1 per 2,200 to 4,300 births; it is slightly more common among males (55%) and slightly more common on the right (53%) than on the left [13]. Among males, 5% have ipsilateral or bilateral undescended testes [14]. With widely available antenatal ultrasound screening, MCDK is now increasingly diagnosed before birth but follow-up postnatal ultrasonography is needed to distinguish MCDK from high-grade urinary tract obstruction from ureteropelvic junction obstruction.

Since MCDK is typically unilateral, the long-term renal prognosis depends primarily on the integrity of the contralateral kidney. After long-term follow-up, 2/40 Italian and 2/34 Indian MCDK patients eventually developed end-stage renal failure [15, 16]. In most cases, the estimated glomerular filtration rate is normal, ranging from 86 to 122 ml/min/1.73 m^2 during childhood [17]. About one quarter of the contralateral kidneys have low grade vesicoureteral reflux, grade I–III; therefore, routine cystourethrogram is not usually indicated unless the patient has recurrent urinary tract infections. Less often, the contralateral kidney has ureteropelvic junction obstruction (3–5%) or ureterovesical junction obstruction (2%). In several large series, there were a small number of contralateral kidneys (2–5%) which exhibited severe reflux, remained small and hyperechoic and failed to show normal compensatory hypertrophy. Children with these findings in the contralateral kidney exhibit mild proteinuria (5–30%) and have the highest risk of progressing to end-stage renal failure [18]. Since the MCDK is usually non-functional, this mild proteinuria presumably arises from the contralateral kidney. Hypertension occurs in a small fraction (1–6%) of cases [19], and is usually associated with minimal residual functional parenchyma (noted by renal scan) in the MCDK. Importantly, hypertension is often reported to resolve when the MCDK is resected.

The etiology of the MCDK is unclear but presumably involves a disturbance when the primordial nephrons become linked to the collecting duct system. Importantly, increased gene copy number variation is seen in >10% of MCDK patients [20]. MCDK has also been associated with heterozygous mutations of the *HNF1β* gene (see below) [21].

Renal hypoplasia is another congenital anomaly of the kidneys and typically refers to kidneys that are reduced in size (2 standard deviations below the expected mean when correlated with age or body height). Hypoplastic kidneys usually

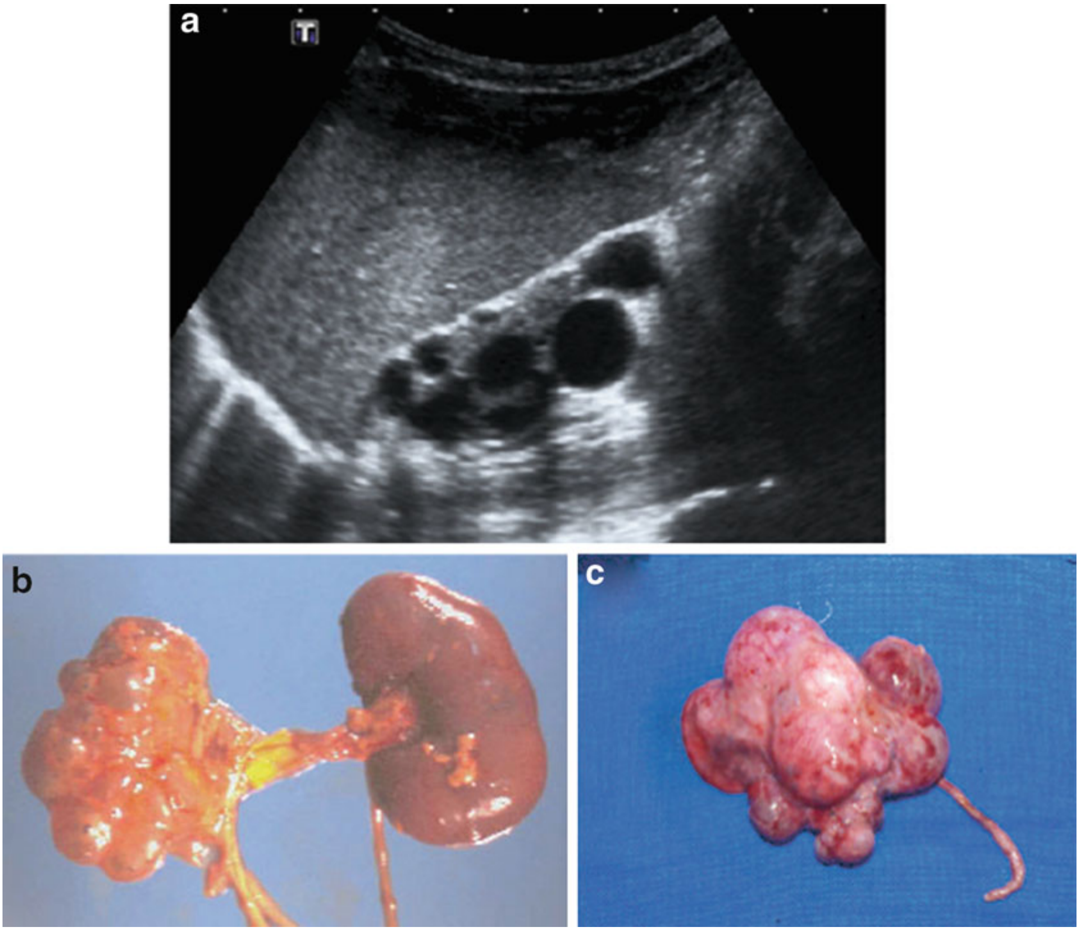

Fig. 3 Multicystic dysplastic kidney. (**a**) Multicystic dysplastic on renal ultrasound imaging (**b**) Multicystic dysplastic kidney (*left*) and normal kidney (*right*) en bloc; (**c**) Multicystic dysplastic kidney in situ

exhibit normal morphology but have reduced nephron numbers. Malformed kidneys may also show features of tissue maldifferentiation with or without cystic change and this is defined as renal dysplasia (Figs. 4, 5, and 6). In fact, renal hypoplasia and dysplasia can only be distinguished based on histopathological assessment of renal tissue, which is rarely performed because the distinction is mostly of academic interest. Both pathologies are risk factors for end stage renal disease, especially if there is bilateral renal involvement. The diagnosis of renal hypoplasia or dysplasia is most commonly made based on the findings on ultrasound imaging: the renal hypoplastic kidney will be small in length, while the dysplastic kidney will be hyperechoic, may be small and may exhibit cystic features. A nuclear medicine scan may also support the diagnosis of renal dysplasia (complete or regional) if it reveals a diffuse loss of isotope uptake or if it reveals specific regions where there is no uptake.

Renal Hyperechogenicity and Parenchymal Cysts

At the 20–22-week gestational ultrasound, radiologists may report hyperechogenicity in one or both kidneys, obscuring normal cortico-medullary differentiation. This often represents renal dysplasia associated with microcystic renal disease, since sub-millimetric parenchymal cysts reflect the ultrasound waves at each fluid/solid surface. However, occasional macrocysts (>1 cm diameter) may also be present. Several clinical features can help distinguish the various forms of cystic renal disease that can be identified by antenatal ultrasound [22]. Because of the substantial phenotypic overlap between these genetically heterogeneous subtypes, diagnostic accuracy may be improved by performing a genetic screen for copy number variants and a broad multiplex gene panel (up to 100 genes) to screen for mutations in genes previously associated with renal cysts and/or dysplasia.

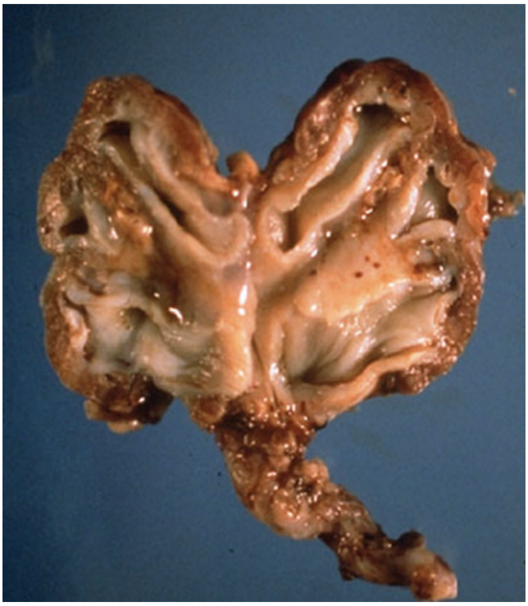

Fig. 4 Image of hypoplastic/dysplastic kidney with bisected pelvis

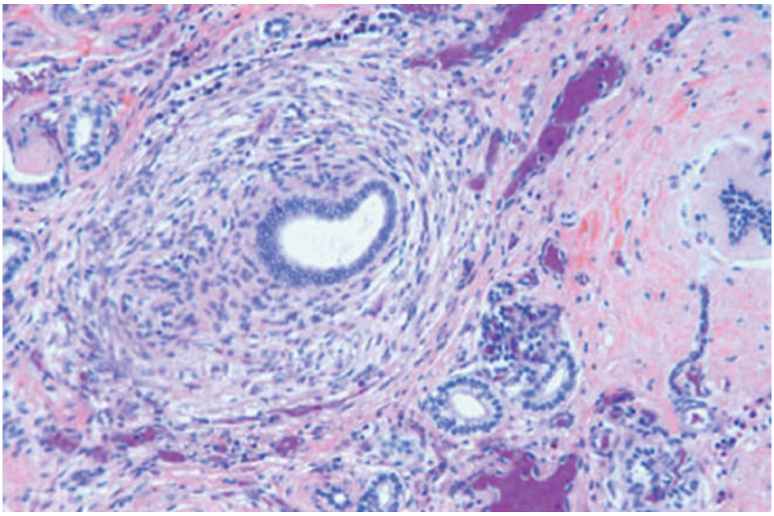
ARPKD (biallelic mutations of the *PHKD1* gene) represents the classic example of antenatal heterogeneous, hyperechoic kidneys (see ▶ Chap. 50, "Autosomal Recessive Polycystic Kidney Disease"). Both kidneys are typically massively enlarged (3–4 standard deviations above the mean) due to diffuse dilatation of distal collecting tubules (<2 mm diameter) but occasional macrocysts >1 cm may also be seen. Severe ARPKD is often evident by 16 weeks gestation, but the presentation is variable. At the 20–22-week screening ultrasound, amniotic fluid may be normal or reduced; serial ultrasounds are crucial to track progressive reduction in amniotic fluid index (AFI) and lung development, since these issues will influence viability in the perinatal period.

ADPKD (germline heterozygous mutations of the *PKD1* or *PKD2* genes) was previously considered to be a cystic kidney disease of adults, although it is now clear that cystogenesis begins in utero and a subset of patients develop macrocysts in late gestation (3%) or in the early pediatric years (up to 23%) (see ▶ Chap. 49, "Autosomal Dominant Polycystic Kidney Disease"). Antenatal ultrasound may show kidney enlargement, often two standard deviations above the mean in 50%, although the size increase is not usually as extreme as in ARPKD and amniotic fluid is

Fig. 5 Histological image showing peritubular fibrous cuff in an area of renal dysplasia



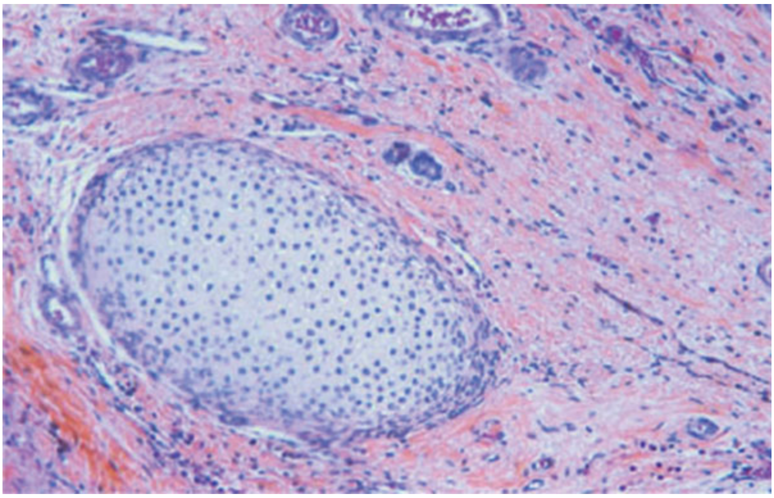


Fig. 6 Histological image showing ectopic cartilage in an area of renal dysplasia

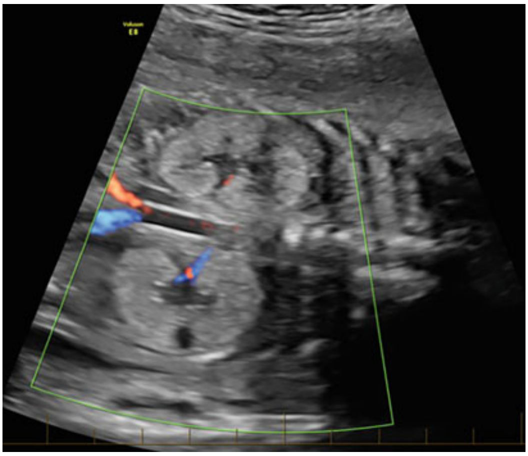

Fig. 7 Ultrasound image of a fetus with hyperechoic kidneys with cysts due to a mutation in HNF1b

typically normal [23]. Multiple antenatal macrocysts (>1 cm diameter) are more commonly seen than in ARPKD. Interestingly, antenatal ADPKD may occasionally mimic ARPKD, especially when the affected fetus harbors biallelic mutations in *PKD1* [24].

Mutations of the *HNF1β* gene are the most common cause of antenatal hyperechoic kidneys on ultrasound imaging [25] (Fig. 7). Nephromegaly and "bright" renal parenchyma may be evident as early as 13 weeks; occasional macrocysts (>1 cm) may appear later in gestation. Amniotic fluid volume usually remains normal in utero and progressive renal insufficiency is unusual before 20 years of age. The highly variable renal phenotype, involving hyperuricemia and diabetes mellitus in young adults, is discussed later in the chapter (see also ▶ Chap. 53, "Autosomal Dominant Tubulointerstitial Kidney Disease").

Renal Ectopia and Fusion Anomalies

During embryogenesis, the two kidneys ascend from a low pelvic position to their normal upper intra-abdominal location. Disturbance of renal ascent leads to renal ectopia in about 1:900 births and is usually (90%) unilateral. The associated ureter nearly always enters the bladder normally, but about half are associated with hydronephrosis. This may be due to ureteropelvic junction obstruction, ureterovesical junction obstruction, or vesicoureteral reflux [26]. In about 40% of cases, the ectopic kidney is found in the pelvis. While most ectopic kidneys are asymptomatic, ectopic kidneys in the lumbar region are sometimes associated with poorly localized pain. Rarely, ectopic kidneys have been reported in the thorax and are identified as an incidental non-functional chest mass.

When aberrant ascent brings them into contact, the two kidneys may fuse. Most commonly, this occurs in the midline and is referred to as a horseshoe kidney (Fig. 8). In 95% of cases, the horseshoe kidney is low-lying (L3-L4) because further ascent has been blocked by the inferior mesenteric artery. The two moieties are fused via a

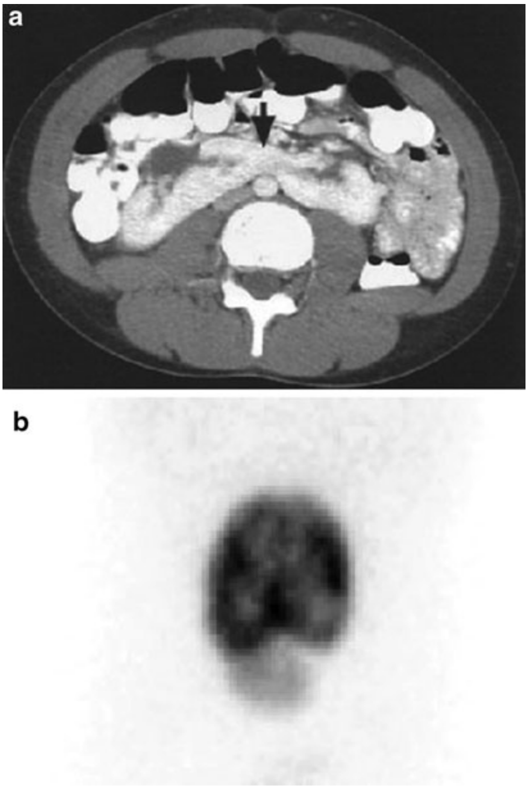

Fig. 8 Horseshoe kidneys: (**a**) Computerized tomography scan showing isthmus of horseshoe kidney fused in midline, (**b**) DMSA scan showing pancake kidney fused in the midline

parenchymal isthmus bridging their lower poles and may develop a variety of vascular arrangements, including a single artery [27]. About half of horseshoe kidneys exhibit vesicoureteral reflux and this can be associated with recurrent urinary tract infections [28]. Patients with horseshoe kidneys are more likely to develop kidney stones at some point during their life. There are occasionally VACTERL (3%) and reproductive tract (5%) anomalies seen in patients with horseshoe kidneys [29]. Although there are rare case reports of renal cell carcinoma arising within horseshoe kidneys, there is no evidence that this occurs more frequently than in the general population. In contrast, patients with horseshoe kidneys do have an increased risk of Wilms' tumor [30]. Between 15% and 30% of girls with Turner syndrome have horseshoe kidneys [31].

Crossed ectopia occurs when one kidney crosses the midline in relationship to the side where its ureter enters the bladder; in 90% of cases, the upper pole of the ectopic kidney is fused to the lower pole of the orthotopic kidney but sometimes this occurs without fusion, and the two kidneys may even exchange sides. Abnormalities of the reproductive tracts are seen in about half of the cases; these include cryptorchidism or absence of the vas deferens in males and vaginal atresia or unilateral uterine abnormalities in females [32].

Diagnosis and Imaging of Congenital Anomalies of the Kidneys

The presence of congenital anomalies of the kidneys is usually suspected from antenatal ultrasound imaging. Standardized antenatal ultrasound reports include several key renal data:

Amniotic Fluid Index (AFI) and Maximal Vertical Pocket (MFP)

During the first 20 weeks of gestation, the amniotic fluid is primarily made up of lung secretions and hydrostatic and osmotic transport of maternal plasma across fetal membranes into the amniotic cavity. By 16 weeks, fetal urine has become the dominant contributor to amniotic fluid. At the time of the 20–22-week ultrasound, fetal urine contributes about 7–10 ml/kg/h to the total volume, while lung secretions contribute about 100 ml/24 h. In counterbalance to this, fetal swallowing removes amniotic fluid up to a rate of 1 L/24 h. Amniotic fluid resorption is also resorbed directly across the amnion into the fetal circulation (intramembranous absorption). Thus, the entire amniotic fluid volume turns over in a 24-h period and steady-state amniotic fluid volume reflects the balance of these processes. Mean amniotic fluid volume increases from about 400 ml at 20 weeks to about 800 ml (range 400–1800 ml) at 32–34 weeks, and then falls gradually to 600 ml at 40 weeks [33].

Table 1 Amniotic fluid index at various gestational ages. Amniotic fluid index (AFI) is calculated by antenatal ultrasonography as the sum of the largest vertical diameter (cm) of amniotic fluid in each of the four quadrants in the image. Mean (50th percentile) and lower limit (2.5th percentile) for various gestational ages are adapted from Moore et al. [35]

AFI (cm)	50th percentile	2.5th percentile
16	12.1	7.3
20	14.1	8.6
25	14.7	8.9
30	14.5	8.2
35	14.0	7.0
40	12.3	6.3

Although amniotic fluid volume cannot be measured precisely in most clinical settings, it can be estimated by transabdominal ultrasonography after 20 weeks gestation. The images of the uterus are divided into four quadrants and, with the transabdominal ultrasound probe held in the sagittal plane, the longest vertical fluid diameters in each quadrant are summed. AFI peaks at about 14–15 cm at 34–38 weeks gestation and then falls to about 11 cm by 40 weeks [34]. Nomograms for AFI in healthy pregnancies as reported by Moore are summarized in Table 1 [35]. By 34–38 weeks, oligohydramnios = AFI<5 cm, low-normal = AFI 5–8 cm, normal = 5–25 cm and polyhydramnios = AFI>25 cm. Alternatively, amniotic fluid volume can be assessed by reporting the Maximal Vertical Pocket (among the 4 quadrants). Normal MVP ranges from 2–8 cm while oligohydramnios = MVP<2 cm. Some clinicians feel that the AFI may underestimate oligohydramnios; therefore, both measurements are often reported. Although oligohydramnios often represents a clinically significant reduction in functional renal mass, it should be noted that it can also be seen with premature rupture of fetal membranes, fetal growth restriction and fetal hypoxia (thought to cause fetal vasopressin release).

Kidney Size

Ultrasound estimates of renal size are important measures of nephron endowment between 20 and 40 weeks gestation. During the first months of postnatal life, compensatory renal hypertrophy may gradually mask the initial relationship between kidney volume and nephron number. Interpretation of this parameter in the antenatal ultrasound report requires access to normative values at different gestational ages. Table 2 summarizes mean renal length (+/− 2 standard deviations) at various gestational ages [36].

Antenatal Imaging

The second trimester ultrasound has a sensitivity of 73–81% and a specificity of 99% in establishing the diagnosis of CAKUT [37]. The sensitivity of ultrasound imaging is highly dependent on the operator's skills and the biological characteristics of the mother and the fetus. For example, it may be difficult to discern fetal anomalies in obese mothers or in the setting of oligo/anhydramnios. This is important because maternal obesity (BMI$\geq$30 kg/m^2) is a risk factor for CAKUT [38]. Oligohydramnios or anhydramnios results in a fetus that is not mobile and there is poor separation of tissue-to-tissue interfaces because of the lack of amniotic fluid: both factors result in poor assessment of fetal anatomy by ultrasound. The poor resolution of fetal anatomy in the setting of oligo/anhydramnios has led to attempts to improve ultrasound imaging by performing diagnostic amnioinfusion.

Fetal magnetic resonance imaging is an important modality to consider in the setting of oligo/anhydramnios because low amniotic fluid is less problematic for image quality (see also ▶ Chap. 6, "Imaging Kidneys and the Urinary Tract"). The kidneys, ureters and bladder can be correctly identified from week 20 onwards by MRI. High quality images can be obtained independent of maternal body habitus, fetal position, or the volume of amniotic fluid. MRI is especially useful to define complex urogenital pathology, to locate ectopic kidneys, to assess for other organ disease, and to differentiate between the urinary tract and the distal intestine as in megacystis microcolon intestinal hypoperistalsis syndrome [39]. There do

Table 2 Kidney size by gestational age. Sagittal kidney length and renal volumes at various gestational ages; mean (50th percentile) and lower limit of normal (5th percentile) are shown. (Adapted from van Vuuren et al. [36])

Gestational age (weeks)	*Kidney length (mm)*		*Kidney volume (ml)*	
	50th %	5th %	50th %	5th %
15	12.5	10	–	–
20	20	16	2	1.5
25	26	23	4	2.5
30	33	28	7	4
35	38	34	12	7.5
40	44	38	17	11

not appear to be any harmful effects to the fetus from MRI even when exposed to electromagnetic fields up to 1.5 tesla (T), although ongoing long-term follow-up is needed [40]. Gadolinium should be avoided as a contrast agent for fetal MRI since there is evidence that it crosses the placenta and accumulates in the fetal circulation and in the amniotic fluid.

Antenatal ultrasound imaging remains the major modality for the diagnosis of CAKUT. Melo et al. were able to identify 76% of patients with CAKUT from antenatal ultrasound imaging; however they did not report at what timepoint they were able to establish the diagnosis [41]. Similarly, Policiano et al. were able to establish a prenatal diagnosis of CAKUT in 88.8% of the cases at a median gestational age of 23 weeks (range 11–40 weeks) [42]. While ultrasound remains an excellent method to define the anatomy of CAKUT antenatally, it does not reliably predict postnatal renal function. Fetal renal hyperechogenicity, when the kidneys appear brighter than the liver, can arise from interstitial infiltration, sclerosis, or microcysts in the cortex or in the medulla. In a follow-up of 43 fetuses referred because of bilateral hyperechogenicity, the majority had ARPKD (20 cases), while 8 cases were diagnosed with ADPKD and 7 cases had another CAKUT disorder. The authors concluded that the diagnosis could not be established by prenatal ultrasound in the absence of a family history and that severe oligohydramnios, amniotic pocket less than 2 cm, and large kidney size (>4 standard deviations as seen with ARPKD) were indicative of a poor postnatal renal outcome [43]. Morris et al. performed a systematic review to determine if antenatal ultrasound could predict renal outcome in congenital urinary tract obstruction. Oligohydramnios, renal echogenicity of the parenchyma, or renal cystic change in the cortex were all correlated with poor renal function postnatally, defined as a serum creatinine >106 μmol/L [44]. Many of the studies that were included in the review had limitations as they did not define oligohydramnios.

Oligo/anhydramnios and Consequences

Oligo/anhydramnios from CAKUT is associated with a high incidence of fetal death in utero, severe pulmonary hypoplasia, umbilical cord compression and perinatal asphyxia. The earlier that renal oligohydramnios (ROH) is identified in the pregnancy, the more severe the pulmonary hypoplasia: Klaassen et al. showed that ROH detected before 30 weeks was associated with a higher risk of mortality [45]. Similarly, Mehler et al. showed that non-surviving babies with CAKUT were diagnosed with ROH on average at 25 weeks compared to 31 weeks in survivors [46]. Pulmonary hypoplasia is a disorder of development in which there is a deficiency in the number of lung cells, airways, and alveoli, ultimately leading to a reduced surface area for gas exchange. From post-mortem studies, pulmonary hypoplasia is defined as a decrease in the lung to body weight ratio, <0.12 (67% of mean normal ratio), and a reduction in the radial alveolar counts, <4.1 (75% of mean normal count) [47]. Postnatally, pulmonary hypoplasia can be suspected in cases of ROH when there is respiratory failure with the need for high ventilatory support and the chest x-ray reveals a bell-shaped chest, an elevated diaphragm, and/or pneumomediastinum or pneumothorax. The challenge is how to define pulmonary hypoplasia prenatally to provide accurate information to counsel families on their baby's postnatal renal and respiratory function. While ultrasound and MRI have been used to assess lung volumes antenatally, there is no consensus on whether they are reliable predictors of pulmonary hypoplasia postnatally.

Several fetal biochemical markers have been studied to determine if they predict postnatal renal function. Fetal urine electrolytes including urine sodium, chloride, and urine osmolarity have been assessed, but they lack sensitivity [48]. β2 microglobulin and Cystatin C do not cross the placenta and therefore, fetal blood or urine samples of these biomarkers should correlate with fetal renal function. Spaggiari et al. measured fetal blood β2 microglobulin levels in 34 fetuses and found that a serum level >5 mg/L predicted a poor renal outcome in 87.1% of cases [49]. This is a relatively small sample and in 62% of the cases, the pregnancy was terminated, therefore further studies are needed to validate its use. Most recently, amniotic fluid samples were analyzed from 140 fetuses with CAKUT and this led to the discovery of a 98-peptide signature that correlated with CAKUT [50]. The 98-peptide signature was characterized by the presence of extracellular matrix fragments and the protein known as actin binding protein thymosin-β4. When thymosin-β4 was knocked out in zebrafish, proximal and distal tubular nephron formation was disrupted, suggesting this protein may be a marker of tubule maturation.

Once CAKUT has been identified during the pregnancy, it is important to screen for other organ abnormalities. Melo et al. demonstrated that neonates with CAKUT in addition to chromosomal syndromes, non-chromosomal syndromes, VATER, or any organ defect had a much higher risk of neonatal mortality (Odds ratio 20.7, 95% confidence interval) [41]. The same group also found that fetuses diagnosed with CAKUT and multiple malformations and chromosomal defects had a neonatal mortality rate of 76% [51]. Indeed if other organ morbidities are identified or there is oligohydramnios, then it is imperative that there is shared decision making between the parents and health care team regarding the implications of these findings to establish a plan of action for either termination of pregnancy, or palliation at the time of birth, or treatment [52].

When isolated CAKUT or CAKUT with other organ defects is suspected on the antenatal ultrasound, genetic counseling and referral to a multidisciplinary team should be offered. As outlined by Talati et al., an individualized approach that is in accordance with the parental wishes for more information is advised [53]. A screen for gross chromosomal abnormalities using a chromosomal microarray can be performed from the amniotic fluid (if less than 25 weeks) or from fetal blood (>than 25 weeks or severe oligohydramnios). If the chromosomal microarray is normal, then a targeted gene panel or whole exome sequencing (WES) on both parents and the fetus could be considered. Large cohort studies of affected fetuses are needed to clarify the benefit of WES or targeted gene panels for prenatal diagnosis and treatment.

In the setting of severe CAKUT with and without other organ defects, termination of the pregnancy must be considered and discussed with the parents. In most cases, the findings from ultrasound will provide sufficient information to guide decision-making. Legal limits for when termination of pregnancy can occur vary between countries, and sometimes even within countries, there are regional differences for when this can occur during gestation. These are difficult discussions and when available, a palliative care team can be beneficial to provide support to the family and the treating team. If there is a neonatal demise or a termination of pregnancy, it can be informative to perform an autopsy and obtain DNA for genetic testing to inform the parents about their risk for future pregnancies.

Treatment of Congenital Anomalies of the Kidney with Oligohydramnios

CAKUT with renal oligohydramnios due to lower urinary tract obstruction or renal agenesis has a poor outcome with high mortality. Vesicoamniotic shunting has been used as a treatment for CAKUT with lower urinary tract obstruction and may have benefit. Clearly, this type of intervention is of no benefit if oligo/anhydramnios is secondary to bilateral renal agenesis or severe renal hypodysplasia with decreased fetal urine production. Serial amnioinfusions have been used to treat fetuses with no or low fetal urine production to palliate pulmonary hypoplasia and reduce the risk of newborn mortality. A recent review of serial amnioinfusions identified a total of 22 fetuses that have been treated: 7 with lower urinary tract obstruction, 8 with congenital renal anomalies, and 7 with lower urinary tract obstruction and congenital renal anomalies [54]. The median number of amnioinfusions was 7 and the median time for the first infusion was at 23 weeks gestation. Impressively, the median age of newborns at delivery was 32 weeks gestation. Of the 22 neonates, 11 survived for at least 1 month, 16 received peritoneal dialysis and 9 went on to receive a renal transplant. Importantly 8 did not require intubation and survived at least until 1 month of age. At present, there is a need for further research to demonstrate efficacy and beneficence.

Genetics of Congenital Kidney Anomalies

Complex Phenotypes from Variable Genetic Backgrounds

From a clinical perspective, determining the etiology of developmental defects can result in more precise diagnostic classification and in the future, this may drive therapeutic strategies to change the clinical outcome of these disorders [55]. The advent of next generation sequencing techniques has redefined the molecular landscape of congenital kidney defects over the last two decades. Next generation sequencing (NGS) approaches are based on automated massive parallel sequencing using clonally amplified DNA templates, allowing quick assessment of an entire human genome. Before the introduction of next generation sequencing, Sanger sequencing (i.e., individual sequencing reactions) of the locus of interest was primarily used for gene discovery in human diseases, but the short reads of <1 kb per sequence and the low throughput of this technique limited testing of multiple variants at once. Nevertheless, most genetic mutations that cause congenital kidney anomalies have been discovered using Sanger sequencing.

Genetic studies of congenital kidney malformations have resulted in the identification of more than 50 genes that have been implicated in syndromic (complex) or isolated forms of congenital kidney defects (Table 3) [55]. While this number continues to grow, a recent report has indicated that there is an extremely high rate of pathogenic variants in individuals self-reported to be healthy and without kidney disease [56]. This suggests that there is a need for more stringent curation of variants and long-term follow-up of individuals with these variants to avoid genetic misdiagnosis.

Many disease-causing genes in congenital kidney anomalies encode transcription factors or signaling molecules that are required for the interaction between the ureteric bud and metanephric mesenchyme during kidney development (see also ▶ Chap. 1, "Pre-natal Development of the Kidneys and Urinary Tract"). There is tremendous heterogeneity in the etiology of congenital kidney anomalies. In addition, incomplete or non-penetrance of gene mutations is commonly observed in affected families. Identical pathogenic mutations can result in completely different CAKUT phenotypes, even between individuals within the same family. Taken together, there is variable expressivity of gene mutations implicated in CAKUT. As noted previously, co-occurrence of urinary tract defects including obstructive uropathy, VUR, or lower urinary tract obstruction is frequently seen with congenital kidney defects. For example, 20–30% of individuals with unilateral renal agenesis or MCDK have a urinary tract malformation [8, 13]. It is not clear what causes the genetic and phenotypic variation of CAKUT, but one can hypothesize that other genetic factors like oligo- or polygenic inheritance, epigenetic changes and/or environmental factors contribute to the variation [57].

Table 3 Glossary of genes associated with congenital kidney defects

OMIM	Gene symbol	Gene product	Gene/Protein family and function	Extrarenal findings/syndrome diagnosis
#106180	*ACE*	Angiotensinogen	Renin substrate	Renal tubular dysgenesis
#106150	*AGT*	Angiotensin-converting enzyme	Zinc metalloproteinase enzyme	Renal tubular dysgenesis
#106165	*AGTR1*	Angiotensin II receptor type 1	GPCR	Renal tubular dysgenesis-
#617298	*AIFM3*	Apoptosis-inducing factor 3	Oxidoreductase	DiGeorge syndrome
#112262	*BMP4*	Bone morphogenetic protein 4	TGF-beta	Cleft lip, microphthalmia
#608892	*CHD7*	Chromodomain helicase DNA binding protein 7	SNF2/RAD54 helicase	CHARGE
#613039	*CHD1L*	Chromodomain helicase DNA binding protein 1 like	SNF2/RAD54 helicase	Cryptorchidism
#600856	*CDKN1C*	Cyclin dependent kinase inhibitor 1C	CDI family	Beckwith-Wiedemann
#118494	*CHRM3*	Cholinergic receptor muscarinic 3	Muscarinic acetylcholine receptor	Prune-Belly-like phenotype
#600140	*CREBBP*	CREB binding protein	Histone acetyltransferase	Rubinstein-Taybi
#602007	*CRKL*	CRK-like protein	Protein kinase	DiGeorge syndrome
#602858	*DHCR7*	7-Dehydrocholesterol reductase	ERG4/ERG24 family, cholesterol biosynthesis	Smith-Lemli-Opitz
#612666	*DSTYK*	Dual serine/threonine and tyrosine protein kinase	Protein kinase superfamily	Seizures (?)
#600855	*DYRK1A*	Dual specificity tyrosine phosphorylation regulated kinase 1A	Protein kinase superfamily	Intellectual disability
#601653	*EYA1*	Eyes absent homolog 1	EYA1 proteins	Branchio-oto-renal
#605558	*FGF20*	Fibroblast growth factor 20	Heparin-binding growth factors family	–
#136350	*FGFR1*	Fibroblast growth factor receptor 1	Protein kinase superfamily	Hypogonadotropic hypogonadism with or without anosmia
#601090	*FOXC1*	Forkhead box C1	Forkhead family of transcription factors	Axenfeld-Rieger syndrome,
#605515	*FOXP1*	Forkhead box P1	Forkhead family of transcription factors	Structural brain abnormalities, seizures, skeletal abnormalities
#607830	*FRAS1*	Fraser syndrome 1	Extracellular matrix protein	Fraser
#608944	*FREM1*	Fraser syndrome 2	Extracellular matrix protein	Fraser
#608945	*FREM2*	FRAS1-related extracellular matrix 2	Extracellular matrix protein	Fraser
#131320	*GATA3*	GATA3	Transcription factor with GATA zinc-fingers	Hypothyroidism, sensorial deafness

(continued)

Table 3 (continued)

OMIM	Gene symbol	Gene product	Gene/Protein family and function	Extrarenal findings/syndrome diagnosis
#146255	*GLI3*	GLI family zinc finger 3	Transcription factor	Pallister-Hall
#617782	*GREB1L*	Greb1-like retinoic acid receptor coactivator	GREB1 family	Mayer-Rokitansky-Kuster-Hauser (presumed)
#300037	*GPC3*	Glypican 3	Cell surface heparin sulfate proteoglycan	Simpson-Golabi-Behmel
#605310	*7-HCR*	Alpha-helix coiled-coil	Role in DNA repair and	–
#189907	*HNF1β*	Hepatocyte nuclear factor 1-beta	Homeobox transcription factor	Renal cysts and diabetes (RCAD)
#611177	*IFT80*	Intraflagellar transport 80	Sensory cilia motility factor	Jeune syndrome
#601920	*JAG1*	JAGGED1	Notch receptor ligand	Alagille
#300836	*KAL1 or ANOS1*	Anosmin-1	Regulates migration of nerve cell precursors	Hypogonadotropic hypogonadism with or without anosmia
#602113	*KMT2D*	Lysine methyltransferase 2D	Histone-lysine methyltransferase family	Kabuki
#300128	*KDM6A*	Lysine demethylase 6A	Lysine-specific demethylase	Kabuki
#151443	*LIFR*	LIF receptor subunit alpha	type I cytokine receptor family	Stuve-Wiedemann syndrome/ Schwartz-Jampel type 2 syndrome
#142994	*MNX1*	Motor neuron and pancreas homeobox 1	Homeobox domain transcription factor	VACTERL/ Caudal regression / Currarino
#6002756	*NOTCH2*	Notch receptor 2	Notch family of transmembrane proteins	Alagille
#608667	*NIPBL*	NIPBL cohesin loading factor	Cohesin loading onto chromatids	Cornelia de Lange
#602490	*NRIP1*	Nuclear receptor interacting protein 1	Modulates transcriptional activity of the estrogen receptor	
#600856	*P57KIP2*	Cyclin-dependent kinase	Cell cycle inhibitor	Beckwith-Wiedemann
#167409	*PAX2*	Paired box 2	Transcription factor	Papillorenal syndrome
#176310	*PBX1*	Pre-B cell leukemia transcription factor	Transcription factor	CAKUT, hearing loss, abnormal ears, or developmental delay
#214100	*PEX1*	Peroxin 1	Peroxisomal ATP-ases	Zellweger
#179820	*REN*	Renin	Enzyme that cleaves AGT to produce Ang I	Renal tubular dysgenesis
#602218	*SALL1*	Sal-like 1	Zinc finger transcription	Townes-Brocks
#607343	*SALL4*	Sal-like 4	Zinc finger transcription	Duane-radial ray
#603961	*SEMA3A*	Semaphorin 3A	Semaphorin family	Hypogonadotropic hypogonadism with or without anosmia
#601205	*SIX1*	Sine oculis homeobox 1	Homeobox transcription factors	Branchio-oto-renal

(continued)

Table 3 (continued)

OMIM	Gene symbol	Gene product	Gene/Protein family and function	Extrarenal findings/syndrome diagnosis
#604994	*SIX2*	Sine oculis homeobox 2	Homeobox transcription factors	–
#600963	*SIX5*	Sine oculis homeobox 1	Homeobox transcription factors	Branchio-oto-renal
#604202	*SNAP29*	Synaptosome associated protein 29	Membrane trafficking	Cerebral dysgenesis, neuropathy, ichthyosis, and palmoplantar keratoderma syndrome / DiGeorge
#608160	*SOX9*	Sex determining region Y-box 9	HMG-box class of DNA binding proteins	Campomelic dysplasia
#600898	*SOX11*	Sex determining region Y-box 9	HMG-box class of DNA binding proteins	Coffin-Siris
#606523	*SRGAP1*	SLIT-ROBO Rho GTPase activating protein 1	GTPase activator	Cleft palate, developmental delay
#609850	*TBC1D1*	TBC1 domain family member 1	GTPase-activating protein	Insulin resistance
#601621	*TBX3*	T-box 3	T-box transcription factor	Ulnar-Mammary
#602427	*TBX6*	T-box 6	T-box transcription factor	Spondylocostal dysostosis
#606219	*TRAP1*	TNF receptor associated protein 1	Heat shock protein 90	VACTERL
#611559	*UPK3A*	Uroplakin 3A	Component of the asymmetric unit membrane	–
#610132	*VANGL1*	VANGL planar cell polarity protein like 1	Vang family	VACTERL / Caudal regression
#603490	*WNT4*	Wnt family member 4	Wnt family of signaling proteins	Mullerian aplasia and hyperandrogenism
#602221	*ZMYM2*	Zinc finger MYM-type containing 2	Zinc finger transcription factor	Skeletal abnormalities, cardiac defects, intellectual disability, dysmorphic facial features

OMIM Online Mendelian Inheritance in Man, *GPCR* G protein-coupled receptor, *CREB* cAMP response element-binding, *HMG* High-Mobility Group, *Ang* Angiotensin

Genetic Perspective on Congenital Kidney Anomalies

Our knowledge of the molecular etiology of congenital kidney anomalies is based on their familial occurrence and the fact that patients with some genetic mutations have a CAKUT phenotype that correlates with a genetically defined animal model. However, the heritability of congenital kidney defects (i.e., the proportion of affected individuals in which genetic factors are causal) remains unknown and systematic studies to estimate heritability have not been performed. Currently, we can establish a molecular diagnosis in 5–30% of affected individuals, but this is highly dependent on the characteristics of the study cohort. The genetics of congenital kidney anomalies can be summarized by three distinct molecular origins:

1. *Rare single nucleotide variants* (SNVs) with large effects cause monogenic disease (Mendelian disorders), i.e., one coding base pair change in a particular gene is deleterious and causes the phenotype. Pathogenic SNVs in CAKUT predominantly follow an autosomal dominant mode of inheritance, however, autosomal recessive and X-linked modes of inheritance have been identified.

2. *Large rare structural variants* (copy number variants or CNVs) have been implicated in 5–10% of isolated and syndromic forms of congenital kidney anomalies. Pathogenic deletions or duplications of multiple base pairs may involve entire chromosomes, multiple genes, or parts of genes that disrupt normal kidney development.
3. *Common variants* (generally caused by non-coding single nucleotide polymorphisms [SNPs]) usually have small effects and have not yet been elucidated in congenital kidney anomalies due to the absence of large cohorts of patients. The oligo/polygenic landscape of congenital kidney defects assumes that multiple genetic defects together give rise to the phenotype. This molecular mechanism is largely unexplored because it requires the integration of genome-wide sequencing data from 10,000 s of patients. However, for other common diseases such as diabetes and inflammatory bowel disease, this approach has been successfully utilized.

Monogenic Disorders

The monogenic basis of congenital kidney anomalies is founded on several observations: (1) Congenital kidney anomalies occur within families, frequently following Mendelian autosomal dominant inheritance patterns. The study of these families has contributed to our current understanding of the genetic basis of congenital anomalies of the kidney and urinary tract. (2) Sporadic kidney malformations often occur as part of a specific genetic syndrome in which multiple developmental defects occur simultaneously in an affected individual (see below). These syndromes are predominantly explained by de novo heterozygous variants with large effects on amino acid translation or heterozygous deletions that disrupt multiple genes. These cases arise sporadically or de novo because the affected individuals often have reduced reproductive fitness, which demonstrates that these variants are under strong selective pressure. The analysis of syndromic disorders characterized by extrarenal manifestations including ocular coloboma, preauricular tags or fistulas, and anorectal malformations in addition to CAKUT, led to the discovery of *HNF1β* (renal cyst and diabetes, OMIM, #137920)*,* *PAX2* (papillorenal syndrome, #120330)*,* *EYA1* (branchio-oto-renal syndrome, #113650), *SALL1* (Townes-Brocks syndrome, #107480), *WT1* (Denys-Drash syndrome, #194080), and others as “syndromic genes.” Follow-up studies have subsequently identified pathogenic variants in the same genes in isolated (non-syndromic) forms of congenital kidney malformations. Homozygous recessive mutations occur predominantly in consanguineous families or from a historical founder effect in isolated populations. Compound heterozygous mutations and X-linked inheritance have also been identified in congenital kidney malformations. Finally, The fact that single-gene knockouts in model organisms (i.e., *Drosophila*, zebrafish and mice) recapitulate the human CAKUT phenotype is further evidence of the causal role of monogenic disease in human kidney defects [57].

The evidence that congenital kidney anomalies are a monogenic disorder was systematically demonstrated in the ESCAPE cohort study in 2006 [58]. Using Sanger sequencing of five candidate genes (i.e., *HNF1β (synonym TCF2)*, *PAX2*, *EYA1*, *SIX1*, and *SALL1*), Weber et al. identified 17 (17%) pathogenic mutations in 100 unrelated families. Of these, 15 were found in *HNF1β* or *PAX2*. Currently, mutations in these genes are still the most common genetic cause of congenital kidney anomalies. Another important finding from the Weber study was that after the genetic diagnosis was established, clinical re-evaluation and family analysis revealed extrarenal syndromic features in 9 of 17 patients. This highlights the additional clinical value of genetic testing.

Mutations of *HNF1β* were initially identified in adults with a genetic form of diabetes (maturity onset of diabetes in the young (MODY) type 5) who were subsequently found to have cystic kidney disease [59]. Individuals with so-called renal cyst and diabetes syndrome (RCAD) typically harbor a pathogenic mutation in *HNF1β* or they carry a microdeletion of chromosome 17q12, which encompasses *HNF1β* (see below). Since its genetic discovery in 1997, the phenotypic spectrum of *HNF1β* mutations has expanded enormously. It includes the entire spectrum of

CAKUT, disorders of pancreatic development including endocrine and exocrine dysfunction, maldevelopment of the female and male genital tracts, neonatal cholestasis and elevated liver enzymes, primary hyperparathyroidism, hyperuricemia, gout, renal magnesium wasting, and sensorineural deafness (see also ▶ Chap. 53, "Autosomal Dominant Tubulointerstitial Kidney Disease"). Approximately 2–30% of affected individuals with congenital kidney anomalies carry pathogenic mutations in *HNF1β* or the microdeletion of chromosome 17q12. In patients with renal cysts and MODY, the prevalence of deleterious mutations in *HNF1β* is even higher at 40% [60]. *HNF1β* has also been widely recognized as the most common monogenic cause of congenital kidney anomalies, particularly in MCDK. Because of the highly variable phenotypes and incomplete penetrance observed in individuals with mutations in *HNF1β*, an *HNF1β* score has been developed based on clinical findings, imaging and biological variables to identify who should undergo genetic testing. A score greater than 8/48 is strongly associated with the identification of a mutation in *HNF1β* [61].

The transcription factor PAX2 is relevant during kidney and eye development. Along with PAX6, PAX2 coordinates the development of the optic vesicle. Sanyanusin et al. were the first to discover a pathogenic mutation in *PAX2* in a family with optic nerve colobomas, kidney hypoplasia, proteinuria, and vesicoureteral reflux [62]. Mutations in *PAX2* lead to congenital kidney defects with or without ophthalmologic manifestations such as retinal coloboma and microphthalmia. Since its initial discovery, the phenotypic spectrum of mutations in *PAX2* has expanded to include sensorineural deafness, skeletal deformities, ovarian teratoma, renal carcinoma, gout, and ventricular septal defects. Vivante et al. reported a heterozygous mutation in *PAX2* in children with steroid-resistant nephrotic syndrome and focal segmental glomerulosclerosis (FSGS) [63], which may be consistent with another group that identified heterozygous mutations in *PAX2* in patients with adult-onset FSGS. Although the potential pathogenic mechanism is unknown, it is plausible that mutations in *PAX2* result in insufficient nephron progenitor cell differentiation and a deficit in nephron formation. This may, in turn, result in hyperfiltration injury with overt proteinuria and FSGS [63]. It is compelling to consider that low nephron number at birth due to a mutation in a gene that is required for kidney development may be at the root of many cases of adult-onset FSGS, hypertension and/or renal failure.

More recently, whole exome sequencing has identified truncating dominant mutations in *GREB1L* (encoding *growth regulation by estrogen in breast cancer 1-like*) as a novel monogenic cause of severe congenital kidney malformations, including bilateral kidney agenesis. When *Grebl1* was knocked out in zebrafish or in the mouse, the kidneys failed to form [64, 65]. In a subset of females with pathogenic mutations in *GREB1L*, developmental defects of the uterus (i.e., agenesis of the uterus, unicornuate uterus) consistent with Mayer-Rokitansky-Kuster-Hauser syndrome have been identified, whereas others only exhibited isolated congenital kidney malformations [65, 66]. *GREB1L,* therefore, has a role during Mullerian organogenesis. The exact function of GREB1L is unknown, but it may function as a coactivator of retinoic acid receptors.

Autosomal recessive inheritance of congenital kidney anomalies is seen with the genes that are implicated in Fraser syndrome. *FRAS1, FREM1, FREM2,* and *GRIP1* all encode extracellular matrix proteins which play a role in cell-cell and cell-matrix interactions between the metanephric mesenchyme and the ureteric bud epithelium. Homozygous truncating mutations in the Fraser complex genes result in Fraser syndrome which encompasses congenital kidney malformations, eye defects, and additional extrarenal features. Interestingly, biallelic missense mutations in these genes have been identified in isolated kidney defects. This is a good example of the impact of specific gene mutations on protein synthesis. Missense mutations result in a full-length protein in which a specific amino acid has been modified (presumably leading to decreased but not absent function) and this results in an isolated kidney defect. In contrast, truncating mutations result in no protein synthesis and this leads to a more extensive phenotype that includes both the renal and the extrarenal features of Fraser syndrome.

Groopman et al. have demonstrated the diagnostic value of next generation sequencing in monogenic kidney disease in 3,037 adults with chronic kidney disease of various etiologies [67]. The authors found the highest diagnostic yield in patients with congenital or cystic kidney disease (23.9%; OR 24.4, 95% confidence interval 10.6–56.4 compared to a reference group of diabetic nephropathy). In a smaller cohort of adults with chronic kidney disease, monogenic causes of CAKUT were identified in 14 out of 114 (12.2%) families containing 138 affected individuals [68]. The variability in diagnostic yield of targeted exome-sequencing studies in specific populations with congenital kidney anomalies is strongly associated with the characteristics of the screening population. For example, while deleterious variants were identified in 20–30% of fetuses with prenatally diagnosed kidney anomalies [69], Nicolaou et al. identified a much smaller contribution of monogenic disorders in a more heterogeneous group of children with CAKUT than expected (6 causal mutations in 453 screened patients, 1.3%) [70]. The yield of genetic screening in children with congenital kidney anomalies will therefore vary based on the phenotype of the cohort, the control population that is used to assess sequence variants and the filtering pipeline that is used to prioritize variants. Targeted gene panels are an important diagnostic tool for cost-effective analysis of the molecular etiology of genetic kidney diseases, however, they have limitations. They do not take into account the possibility of phenocopies (i.e., the phenotype is caused by environmental conditions rather than genetic factors), phenotypic expansion of disease (i.e., the phenotype has not been previously attributed to the disease gene, and hence, is not included in the gene panel) and/or the chance of coincidental diagnosis, meaning the discovery of a gene mutation that is unrelated to the phenotype. For these reasons, it may be more prudent to use whole exome or genome sequencing to evaluate all genes collectively [71]. Of benefit, these more comprehensive genetic tests can be re-analyzed with updated knowledge of pathogenic mechanisms at any given time-point.

Copy-Number Variation

Besides monogenic disorders, congenital kidney anomalies can be attributed to copy-number variants (CNVs), which are defined as any gain or loss of germline DNA ranging from 1,000 basepairs to entire chromosomes (i.e., megabases [Mb]). CNVs influence gene expression, phenotypic variation within the general population, and result in imbalances in gene dosage and/or disruption of genes. CNVs below 1 to 2 Mb are usually not detectable by conventional cytogenetic techniques, but they are readily detected by chromosomal microarrays (array comparative genomic hybridization or SNP arrays), which are the preferred technique for detection of genomic imbalances. CNVs which occur more often in people with the disease of interest are defined as recurrent CNVs. Recurrent CNVs are driven by highly repetitive elements in the human genome and result in recurrent breakpoints in affected individuals. Non-recurrent CNVs have variable breakpoints and are driven by inadequacies in DNA repair mechanisms. There are over 200 recurrent CNVs that underlie human congenital malformations such as neurocognitive disorders, cardiac anomalies, craniofacial malformations, neuropsychiatric disorders and CAKUT. Golzio and Katsanis have proposed a simplex model in which a single gene imbalance within the CNVs is responsible for the genomic disorder (i.e., the chromosome 17q12 microdeletion containing *HNF1β*), and a more complex model in which multiple modifier genes within and/or outside the CNVs determine the constellation of developmental phenotypes [72]. Like syndromic CAKUT caused by single gene defects, pathogenic CNVs display incomplete penetrance and variable expressivity of disease.

Genomic disorders are diseases that are characterized by loss or gain of CNVs. Sanna-Cherchi and Gharavi analyzed a cohort of 522 individuals with kidney hypodysplasia using SNP-arrays and discovered that cases had a much higher burden of large and rare exonic CNVs than controls [73]. In addition, they identified known genomic disorders in 10.1% of patients and potentially pathogenic CNVs in 6.1% of patients. Not surprisingly, the most prevalent genomic disorders were the chromosome 17q12 microdeletion (RCAD locus) and the chromosome 22q11.2 microdeletion (DiGeorge syndrome locus). However, a substantial fraction of known genomic disorders occurred in cases without extrarenal features, supporting the fact that CNVs also exhibit variable expressivity [73].

In a smaller cohort of 80 children with congenital kidney malformations, this higher burden of large and rare CNVs was replicated in cases compared to population controls [74]. Under the assumption of a simplex model in which one gene causes the CNV phenotype, a systematic in silico approach identified *DLG1* and *KIF12* as potential genetic drivers of congenital kidney malformations.

The same team of investigators expanded CNV analyses to the entire spectrum of CAKUT phenotypes ($n = 2{,}824$) of which congenital kidney malformations (kidney hypodysplasia) were the largest group ($n = 1{,}088$) [75]. The authors found that large and rare CNVs were most prevalent in isolated and syndromic forms of congenital kidney malformations when compared to over 21,000 healthy controls (CNVs ≥500 kb OR 2.20, 95% confidence interval 1.79–2.58; *P*-value 5.67×10^{-15}). Interestingly, the enrichment of genomic imbalances was much less pronounced in children with duplex kidneys and even absent in the case of ectopic kidney tissue, suggesting a different molecular basis for these anomalies. Overall, a genomic disorder was diagnosed in 7.3% of individuals with congenital kidney malformations (OR 12.65, 95% confidence interval 9.40–16.94; *P*-value: 8.53×10^{-50} vs. population-based controls). Although unique CNVs occurred, most of the genomic disorders were identified at the following chromosomal locations: 17q12 locus (RCAD), 22q11.2 (DiGeorge), 4p1 (Wolf-Hirschhorn), 16p11.2 and 1q21.1 [75]. In contrast to other CAKUT phenotypes, congenital kidney anomalies were predominantly caused by deletions at the abovementioned loci and not by duplications. This suggests that congenital kidney defects predominantly originate from haploinsufficiency, i.e., a single copy of the wild-type allele is insufficient for formation of normal kidney tissue, or a dominant negative effect in which disruption of a gene adversely affects the normal, wild-type gene product. Approaching the common genomic disorders in congenital kidney anomalies from a one driver gene model has resulted in increasing insight into the molecular etiology of disease. For the chromosome 17q12 locus *HNF1β* is the major driver. For the chromosome 22q11.2 locus, *CRKL* appears to be the major genetic driver for congenital kidney malformations, however the adjacent genes, *AIFM3* and *SNAP3,* may also be implicated [76]. For the chromosome 16p11.2 locus, which is the most prevalent cause of autism spectrum disorder, *KCTD13* has been implicated as the driver of the neurocognitive phenotype [77]. In contrast, the transcription factor *TBX6* has been proposed as the candidate gene driver for the congenital kidney malformations associated with the 16p11.2 microdeletion [75]. This was based on the finding that individuals with mutations in *TBX6* have kidney hypodysplasia. Similar findings were recapitulated in mice with a null mutation in *Tbx6 [75]*. Another group proposed that the transcription factor *MAZ* that regulates urogenital development is the main genetic driver for the kidney phenotype in the 16p11.2 microdeletion [78]. It is possible that a more complex genetic etiology underlies the kidney malformations associated with this genomic disorder.

From a clinical perspective, CNVs are relevant for antenatal diagnostic purposes for two reasons: (1) as highlighted earlier in this chapter, the majority of affected individuals with congenital kidney malformations are now identified in utero, and (2) the a priori chance of finding a genetic etiology for a developmental kidney defects is higher when extrarenal malformations are present. Recent studies in children with a fetal diagnosis of multicystic dysplastic kidney and renal hypodysplasia reported a diagnostic yield of pathogenic CNVs of approximately ~12.5%. Furthermore, Sanna-Cherchi et al. noted substantial overlap with known CNVs causing neurodevelopmental defects and psychiatric disorders, such as autism and schizophrenia [55]. This suggests that children with congenital kidney defects may be at increased risk of intellectual disability as well as other neurocognitive defects. Indeed, subsequent analysis of the Chronic

Kidney Disease in Children (CKiD) study cohort demonstrated that children with pathogenic CNVs had significantly lower neurocognitive scores for domains such as IQ, depression/anxiety, and executive functioning [79]. In summary, chromosomal microarrays should be considered a first line diagnostic test for children with congenital kidney anomalies [80].

Common Variants

Most congenital kidney malformations arise from rare monogenic disorders caused by non-synonymous coding variants with large effects. Common variants that generally consist of non-coding or synonymous coding variants, typically have small effect sizes and therefore much larger cohorts of patients are required to infer causality. Common variants are usually identified by genome-wide association studies (GWAS) using SNP arrays. Since their introduction in the early 2000s, chromosomal microarrays have identified many loci in which the DNA sequence of individuals with kidney disease differs from population-based controls. However, only a handful of these loci have been directly linked to disease causality. This is because often, their biological function is poorly understood, functional validation studies are absent, and/or large differences in allele frequencies exist between populations. These substantial hurdles have limited the use of GWAS to understand congenital kidney malformations. Duplex kidneys and ectopic kidneys may have a genetic background based on common variants given their relatively high prevalence in the population. Knowledge of common variants is an important missing piece in the etiology of congenital kidney malformations. It is conceivable that CAKUT could arise from the combined effects of thousands of common variants at once. By integrating genetic methods, functional modeling of disease, bioinformatic tools and statistical genetic analyses, common variants identified from GWAS can drive the generation of oligo- or polygenic risk scores (PRS). PRS combine the sum of all known variants to calculate an overall risk of developing a particular disease. This approach has been successfully used to understand diseases such as coronary artery disease, inflammatory bowel disease, and diabetes mellitus, and could be applied to better understand CAKUT [81].

Syndromes Associated with CAKUT

Syndromes are characterized by a set of associated signs and symptoms where a genetic cause is known. Human CAKUT is frequently observed as part of a genetic syndrome (Table 4). Importantly, syndromes that are due to ciliopathies like nephronophthisis can phenocopy CAKUT and with the exception of Jeune syndrome are not included in this list (see ▶ Chap. 52, "Nephronophthisis and Related Ciliopathies").

Alagille syndrome (AS; OMIM #118450) is an autosomal dominant disorder characterized by a paucity of interlobular bile ducts, chronic cholestasis, cardiac anomalies, butterfly vertebrae, corneal abnormalities, dysmorphic facies, and cystic renal dysplasia [82]. AS is due to mutations in Jagged-1 *(JAG1)*, which encodes a ligand for the Notch receptor. Jagged ligand/Notch receptor interactions between cells are critical for determination of cell fates during development. Early in kidney development, Notch signaling regulates nephron and collecting duct cell differentiation. Notch signaling represses expression of SIX2 in nephron progenitor cells (NPCs), which causes premature differentiation of NPCs and results in less nephron formation [108]. In collecting duct cells, activated Notch signaling promotes principal cell differentiation at the expense of intercalated cell fates [109]. During the later stages of nephron morphogenesis, loss of Notch signaling promotes the formation of proximal tubular cysts, an increase in epithelial cell proliferation, and renal papillary microadenomas.

Apert syndrome (acrocephalosyndactyly type I, OMIM #101200) is an autosomal dominant disorder characterized by craniofacial defects, maxillary hypoplasia, protruding eyes, hypertelorism, and hydronephrosis [83]. It occurs in 6 to 15.5 out of one million livebirths. Most cases result from activating mutations in the gene encoding *fibroblast growth factor* (*FGF*) *receptor 2* (*FGFR2*), located on chromosome 10 [83]. The FGF family consists of 22 structurally related proteins and plays a central

role in the growth and differentiation of mesenchymal and neuroectodermal cells. Studies in mice demonstrate an important role for FGFR2 in maintaining NPCs, ureteric bud (UB) branching, and ureter and bladder mesenchymal development [110].

Beckwith-Wiedemann syndrome (BWS; OMIM #130650) is a pediatric overgrowth disorder characterized by a predisposition to tumor development. BWS results from dysregulation of imprinted gene expression in the chromosomal region 11p15.5 and in genomic loci outside of this region [84]. The critical BWS genes in the 11p15.5 region include *cyclin-dependent kinase inhibitor 1C* (*CDKN1C/p57KIP2*) that regulates cell cycle progression, *insulin-like growth factor 2* (*IGF2*), *potassium channel voltage-gated KQT-like subfamily member 1* (*KCNQ1*), and *KCNQ1-overlapping transcript 1* (*KCNQ1OT1*, or *long QT intronic transcript 1*). Clinical manifestations of BWS include macrosomia, visceromegaly, macroglossia, hemihyperplasia, omphalocele, ear lobe creases, posterior helical ear pits, and embryonal tumors including Wilms' tumors, hepatoblastomas, and neuroblastomas. Renal abnormalities include congenital anomalies of the kidneys, nephromegaly, collecting system abnormalities, renal cysts, nephrocalcinosis, and medullary sponge kidney [111].

Branchio-oto-renal syndrome (BOR; OMIM #113650) is an autosomal dominant disorder characterized by defects in the derivatives of the branchial arches that give rise to the face, the neck, and the pharynx. BOR syndrome is characterized by cervical fistulas or cysts, ear pits, cochlear hypoplasia, hearing loss, and renal anomalies [85, 112]. The prevalence of BOR syndrome is about 1:40,000 and 2% of affected children have profound deafness. About 40% of patients with BOR syndrome have heterozygous inactivating mutations of the gene that encodes the transcription factor EYA1 on chromosome 8q13 [86]. EYA1 is expressed in nephron progenitor cells (NPC) of the embryonic kidney and in the first branchial arch that gives rise to the external ear, the auditory canal, the ossicles of the ear and the hair cells of the cochlea. Between 5% and 10% of patients with BOR syndrome have mutations in genes belonging to the transcription factor family of SIX proteins. The *EYA1* gene interacts with members of the *SIX* gene family that control expression of the PAX2 and GDNF protein products that are required for specification and/or maintenance of NPCs in the metanephric mesenchyme [113, 114]. Loss of *Six2* in mutant mice results in depletion of the NPCs and renal hypoplasia [115]. To date, one patient with CAKUT has been identified with a pathogenic mutation in *SIX2*: it was not reported if this boy had extrarenal features consistent with BOR syndrome [116]. In BOR syndrome, penetrance is incomplete, and patients may have only one or two features of the syndrome. Renal anomalies are not observed in all patients and may differ between individuals within the same family. Renal findings include renal agenesis or hypoplasia, vesicoureteral reflux (VUR), ureteropelvic junction obstruction (UPJO) and ureteral duplication. Renal hypoplasia ranges from slightly reduced kidney size to bilateral renal agenesis with perinatal death [117]. Only 5–10% of patients with BOR syndrome develop end-stage renal disease.

Campomelic dysplasia (OMIM# 114290) is a rare autosomal dominant condition resulting from a dominant mutation in the *SOX9* gene (*sex-determining protein homeobox 9* mapped to 17q24.3) or from a mutation upstream of the *SOX9* gene [88, 89]. Most cases (77%) are lethal because of respiratory insufficiency from laryngotracheomalacia in combination with a narrowed thorax. Clinical features include hypoplastic scapula and cervical vertebrae, short femur and tibia that are ventrally bowed, dislocated hips, talipes equinovarus (clubfoot), facial abnormalities, including micrognathia and cleft palate (Robin sequence), congenital heart disease, brain defects, and renal abnormalities including hydroureter, renal hypodysplasia, and hydronephrosis [88, 89]. In the developing mouse kidney, SOX9 is expressed in the ureteric bud (UB) tips and the ureteral mesenchyme. Targeted deletion of *Sox9* in the mouse UB results in severe kidney defects ranging from hypoplastic kidneys to renal agenesis [118].

CAKUTHED (OMIM #617641) is an autosomal dominant syndrome of CAKUT with or without hearing loss secondary to mutations in the transcription factor *PBX1* which encodes the *Pre-B cell leukemia transcription factor.* In addition to hearing loss, the outer ear may be malformed and developmental delay is described. Using targeted exome sequencing, Heidet et al. identified five individuals with CAKUT and a de novo pathogenic mutation in *PBX1:* some of these individuals also had deafness and/or developmental delay [87]. *Pbx1* null mice exhibit hypoplastic kidneys, renal agenesis, and poorly defined cortical and medullary regions [119].

DiGeorge syndrome (OMIM #188400) is an autosomal dominant disorder caused by a 1.5–3.0 megabase heterozygous deletion on chromosome 22q11.2. The malformations associated with the deletion include congenital cardiac anomalies, neonatal hypocalcemia from hypoparathyroidism, and thymic hypoplasia. A mild to moderate delay in neurocognitive and psychomotor development is common as well as dysmorphic facial features. Kidney malformations include unilateral renal agenesis, renal dysplasia, and bilateral hydronephrosis [90].

Fraser syndrome (OMIM# 219000, 617666, 617667) is characterized by eyes that are completely covered by skin and usually malformed (cryptophthalmos), fusion of the skin between the fingers and toes (cutaneous syndactyly), and genitourinary anomalies including enlarged clitoris in females, and ambiguous genitalia [91]. The most common urinary tract abnormality in Fraser syndrome is the absence of one or both kidneys. Fraser syndrome results from autosomal recessive mutations in *FRAS1* and *FRAS1-related extracellular matrix* (ECM) *gene 2* (*FREM2*) or *GRIP1*, a scaffolding protein that physically interacts with FRAS1 and FREM2 [120]. Autosomal recessive mutations in the genes implicated in Fraser syndrome are also associated with isolated CAKUT [121]. FRAS1 and FREM2 are extracellular matrix proteins that line the ureteric bud epithelia, Mice lacking *Fras1* develop renal agenesis due to the failure of ureteric bud outgrowth secondary to impaired GDNF expression [122]. The renal phenotype observed in *Fras1* mutant mice can be rescued by decreasing Sprouty activity, which permits FGF-mediated ureteric bud induction [123]. FRAS1 and FREM proteins contribute to epithelial integrity such that mutations in their corresponding genes lead to disrupted dermal-epidermal attachment and embryonic skin blistering [120]. Syndactyly may result from downregulation of MSX2, a transcription factor that stimulates apoptosis and interdigital cell death.

HDR syndrome (hypoparathyroidism, sensorineural deafness and renal disease), also known as Barakat syndrome, is an autosomal dominant form of hypoparathyroidism associated with sensorineural deafness and renal dysplasia (HDR syndrome; OMIM #146255) [92, 93]. HDR syndrome is caused by mutations in the gene encoding GATA binding protein 3 (GATA3), which is localized to chromosome region 10p14–15 [92, 93]. GATA3 is a zinc finger transcription factor that regulates gene expression in many developing tissues such as the parathyroid glands, breast, kidneys, inner ears, and thymus. In the kidney, GATA3 is essential for ureteric bud branching, and mice without *Gata3* fail to develop kidneys. Conditional inactivation of *Gata3* in the nephric duct in mice causes ectopic ureteric budding and a spectrum of urogenital malformations [124]. *Gata3* acts downstream of *β-catenin*, but upstream of *Ret*, to prevent ectopic ureter budding and premature cell differentiation in the nephric duct [124].

Jeune syndrome (also called asphyxiating thoracic dystrophy) (OMIM#611177, 617353) is an autosomal recessive skeletal dysplasia with multiorgan involvement [94]. Some patients have a mutation in the gene, *IFT80* that encodes a protein that is part of the intraflagellar transport complex B, which is critical for the function of sensory and motile cilia [94]. Skeletal abnormalities include short ribs and limbs, narrow thorax, and polydactyly. Patients usually develop progressive respiratory insufficiency in the first few months of life related to the abnormally small thorax. Renal manifestations include cystic kidney disease resulting in renal insufficiency.

Kallman syndrome or idiopathic hypogonadotropic hypogonadism with anosmia (OMIM#300338) is associated with mutations in as many as 25 genes including *ANOS1* or *Anosmin1, FGFR1, FGF8, PROKR2, SPRY4, FGF17, SEMA3A or Semaphorin-3A, IL17RD,* and *FEZF1* [95, 96]. There is marked locus heterogeneity, incomplete penetrance and variable expressivity, and evidence for mutations in multiple genes in some affected families, suggesting oligogenic inheritance. The *ANOS1* gene is located on the X chromosome and encodes the protein anosmin-1 which is found in the extracellular matrix. The clinical phenotype of patients with *ANOS1* mutations is more severe with a higher incidence of microphallus, cryptorchidism, and small testes. The renal phenotype of Kallman syndrome is characterized by unilateral renal agenesis [125]. Semaphorins are secreted guidance proteins that play important roles in organogenesis. In the mouse, SEMA3A regulates vascular patterning in the developing kidney, acting as a negative regulator of endothelial cell migration and survival, and as a negative regulator of ureteric bud branching [126]. Mice with a mutation in *Sema3A* also show abnormal olfactory development [127].

Mammary-ulnar syndrome (OMIM#181450) is an autosomal dominant disorder due to mutations in the *T-box transcription factor 3* (*TBX3*) gene characterized by posterior limb deficiencies or duplications, apocrine/mammary gland hypoplasia, abnormal dentition, delayed puberty in males, genital anomalies, renal dysplasia, and unilateral renal agenesis [97]. Deletion of *Tbx3* in mouse endothelial cells results in glomerular hypoplasia, microaneurysms, and fibrosis in subsets of glomeruli [128].

Mayer-Rokitansky-Kuster-Hauser Syndrome (MRKH, OMIM #277000) is a syndrome that affects 1:5,000 girls. It is characterized by uterovaginal atresia in the setting of a normal female karyotype and is associated with renal agenesis. There is significant phenotypic overlap with another syndrome MURCS which stands for Mullerian duct aplasia, unilateral renal agenesis, and cervicothoracic somite anomalies (OMIM #601076). In a study of 25 patients, Pittock et al. noted that the most common presenting symptom was primary amenorrhea and the mean age of presentation was 16.75 years [98]. Recently, heterozygous mutations in *GREB1L* were identified in fetuses with bilateral renal agenesis and uterovaginal aplasia [66]. The authors observed that mutations in *GREB1L* result in MRKH with incomplete penetrance and therefore, they suggested that there may be a requirement for additional genetic and environmental factors for full penetrance of the phenotype.

Okihiro syndrome, also known as Duane-radial ray syndrome, (OMIM#607323) is an autosomal dominant disorder due to mutations in the *Sal-like 4* (*SALL4*) gene characterized by upper limb, ocular and renal anomalies [99]. Renal anomalies include renal agenesis, crossed fused renal ectopia and VUR [99]. SALL4 is transiently expressed in the nephric duct and ureteric bud during early kidney development in mice.

Pallister-Hall syndrome (PHS, OMIM#146510) is an autosomal dominant disorder characterized by hypothalamic hamartomas, pituitary dysfunction, central polydactyly in which the extra digit is on the ring, middle or index finger, and visceral malformations [100]. Urogenital system defects in individuals with PHS include renal aplasia or hypoplasia, hydroureter, hydronephrosis, or a common urogenital sinus with an imperforate anus [129]. PHS is due to a heterozygous mutation in the *GLI3* gene located on chromosome 7p14 [100]. *GLI3* encodes a zinc finger transcription factor that mediates Sonic hedgehog (SHH) signaling. SHH controls cell fate determination, proliferation and tissue patterning during embryogenesis. Studies in mice demonstrate that urogenital system phenotypes observed in PHS are caused by GLI3R-dependent alterations in nephric duct patterning, ureteric bud branching, and nephron progenitor cell self-renewal [130].

Renal-coloboma syndrome (RCS, OMIM #120330), also known as the papillorenal syndrome, is an autosomal dominant disorder characterized by renal hypoplasia and optic nerve colobomas [62]. Other extrarenal features of RCS include sensorineural hearing loss, Arnold-Chiari malformation, seizures, and joint laxity. Renal malformations include renal hypodysplasia, VUR, and less often, multicystic dysplasia and UPJO [131]. RCS results from mutations in the *Paired box 2* (*PAX2*) gene. PAX2 belongs to a family of PAX DNA-binding proteins that control tissue morphogenesis and embryo patterning. PAX2 has a critical role at multiple steps of kidney and urinary tract development. Most individuals with renal hypoplasia from a mutation in *PAX2* progress to end-stage renal disease (ESRD) [58]. More than 50 heterozygous mutations in the *PAX2* gene have been described in patients with the RCS.

Analysis of genetically modified mouse models has identified renal developmental genes and the gene regulatory networks directing morphogenesis of the urogenital system. In the mouse, *Pax2* null embryos form a nephric duct which later degenerates by apoptosis during the elongation process and thus, they do not form normal mesonephric tubules [132]. As a result, *Pax2*-deficient mouse embryos fail to form metanephric kidneys. Heterozygous inactivation of *Pax2* in the mouse leads to renal hypoplasia and vesicoureteral reflux [133]. The $Pax2^{1\mathrm{Neu}/+}$ mouse model, bearing the same 1-bp frame-shift mutation in *Pax2* as found in a human family with RCS, recapitulates the defects of RCS, including renal hypoplasia, cystic kidneys, and VUR [133]. PAX2 can switch from a positive to a negative regulator of gene transcription through interaction with the co-repressor protein Groucho-related gene 4 (GRG4). In addition, PAX2 can regulate gene transcription through its interactions with Ptip (Pax transactivation domain interacting protein) by recruiting epigenetic complexes to the DNA [134]. Phosphorylated PAX2 recruits Ptip and a complex of H3K4 methyltransferases including the mammalian homologues of Drosophila Trithorax proteins known as MLL (mixed lineage leukemia) that promote chromatin opening and active gene transcription via H3K4 trimethylation

[134]. The downstream targets of PAX2 include genes critical for normal kidney morphogenesis. In the nephric duct, PAX2 regulates the transcription of *GATA3* and *LHX1* which turn on the GDNF (glial derived neurotrophic factor)/RET pathway which is necessary for metanephric kidney induction and UB branching [124, 135]. Later in kidney development, PAX2 has a distinct role in mesenchymal-epithelial transition, specification, and patterning of the surrounding mesenchyme. Based on the analyses of *Pax2* loss of function phenotypes in the mouse, *PAX2* is critical for the development of both the ureteric bud and the metanephric mesenchyme.

Renal cysts and diabetes (RCAD) syndrome (OMIM #137920) is an autosomal dominant disorder caused by mutations of the *TCF2* gene (also called *HNF1β* or *HNF1 Homeobox B*) that encodes hepatocyte nuclear factor-1-β (HNF-1-β) protein [101]. HNF-1-beta protein is a member of the homeodomain-containing superfamily of transcription factors and regulates gene expression in several organs, including the liver, the kidney, the intestine, and the pancreas. Clinical features of RCAD syndrome include renal cysts, diabetes mellitus, elevated liver enzymes, hyperuricemia, pancreatic atrophy/hypoplasia, and genital malformations [136]. There is no correlation between the genotype and the phenotype and there is a high intrafamilial variability of the phenotype. De novo mutations are discovered in 50% of cases [136]. In case series of children with renal cysts, renal hypodysplasia or syndromic CAKUT, mutations of *HNF1β* have been identified in 15–30% of cases [137]. Mutations in *HNF1β* account for 29% of fetuses with hyperechogenic kidneys of normal size or slightly enlarged size and renal cysts are also often observed [25]. In the Decramer study, the most prevalent genetic anomaly was the complete heterozygous deletion of the *HNF1β* gene, which was observed in 83% of cases [25]. The mechanisms by which HNF1β might be involved in renal cystogenesis in humans are unknown. Studies in animal models suggest that HNF1β may control renal cyst formation by regulating genes that are critical for kidney development and ciliogenesis. Targeted removal of *Hnf1β* in mice leads to abnormal ureteric bud branching and defective collecting duct differentiation/patterning which leads to cystogenesis [138]. At a molecular level, *Hnf1β*-deficient mice exhibit reduced expression of key regulators of ureteric bud branching, such as PAX2, RET, GFRA1 and ETV5 [138]. Other animal studies demonstrate that mice with renal-specific inactivation of *Hnf1β* develop polycystic kidney disease. HNF-1β may promote renal cyst formation by regulating the transcription of genes involved in cystogenesis such as *UMOD*, *PKHD1* (polyductin), *PKD2*, and *Polaris* [139]. These genes play a critical role in the formation of cilia.

Renal tubular dysgenesis Homozygous or compound heterozygous mutations in the genes encoding for angiotensinogen (*AGT*), renin, angiotensin-converting enzyme (*ACE*) or angiotensin II receptor type 1 (*AGTR1*) are associated with renal tubular dysgenesis (RTD, OMIM #267430) [102]. The critical role of the renin-angiotensin system (RAS) during kidney development in humans was revealed by the fact that maternal use of ACE inhibitors or ATR1 antagonists during pregnancy causes fetal anuria, oligohydramnios, and low blood pressure in neonates postnatally. All the major components of the RAS are expressed in the human embryonic kidney as early as the fifth week of gestation when metanephric organogenesis commences. To date, 54 distinct mutations have been identified in 48 unrelated families [102, 140]. These mutations appear to be pathogenic because they result in the absence of protein or they modify highly conserved amino acid residues [140]. Affected patients exhibit severe hypotension, which is presumably due to the lack of angiotensin II. Most newborns with RTD die in the perinatal period due to anuria combined with pulmonary hypoplasia secondary to the severe oligohydramnios [141]. Skull ossification defects are frequently observed and result in microcephaly, large fontanelles, and underdeveloped cranial bones. The kidneys are usually of normal size. Glomerular number may be normal, low, or increased, while glomerular size is normal or enlarged. The hallmark of the disease is the absence or the reduction in proximal tubules. Those proximal tubules that are observed are immature and lack a brush border. Typical vascular changes include thickening of the muscular layer of small arteries and arterioles. In the medulla, collapsed CDs and abundant interstitial fibrosis are observed [142]. No correlation has been established between the mutated gene and the clinical course of the disease, suggesting that the disease is not specifically linked to the defect of one or another *RAS* gene, but to low systemic blood pressure, which is the physiological consequence of RAS inactivation.

A single polymorphism, a 1332A>G transition, in the human *AGTR2* gene, that encodes angiotensin II receptor type 2 has been associated with CAKUT in several, but not all, studies. This alteration in the *AGTR2* gene is described in American and German Caucasian males with ureteropelvic junction (UPJ) stenosis, megaureter, and multicystic dysplastic kidney (MCDK) [143]. The same transition was detected in Korean children with unilateral MCDK, renal agenesis, and hydronephrosis [144], and in Italian children with VUR, hypoplastic kidney, UPJ stenosis, nonobstructive megaureter, and posterior urethral valves (PUV) [141]. The difference in phenotypes may be due to an insufficient number of patients studied, limitations in study design, low penetrance of *AGTR2* mutation, the contribution of modifier genes, or other factors. Thus, while *RAS* gene mutations have been clearly linked to patients with RTD, their association with other types of CAKUT in humans remains elusive.

Rubinstein-Taybi syndrome (RTS, OMIM #180849) is an autosomal dominant disease due to a contiguous deletion of chromosome 16 p13.3 that includes the cAMP response element-binding protein (CREB)-binding protein gene, *CREBBP* (also called *CBP*) as well as neighboring genes. Less severe forms of the syndrome are due to point mutations or deletions restricted to the *CBP* gene and account for 50–70% of affected patients. Another gene, *EP300* on chromosome 22q13 accounts for 3% of affected patients [145]. The *EP300* gene encodes the protein p300, which regulates the transcription of many genes and is important in cell proliferation and cell differentiation. Both CBP and p300 are histone acetyltransferase enzymes that remodel chromatin such that transcription factor proteins can bind to genomic DNA. RTS is characterized by short stature, microcephaly, dysmorphic features, broad thumbs and toes, hirsutism, congenital heart disease and intellectual disability [103]. Renal anomalies consist of renal hypoplasia and agenesis. Homozygous removal of *Cbp* or *p300* in the mouse leads to an embryonic lethal phenotype prior to kidney formation. The cAMP pathway has been shown to be important for the release of renin and the differentiation of renin-producing cells. Indeed, conditional deletion of *Cbp* and *p300* in renin-expressing cells in mice results in severe kidney abnormalities which include an absence of renin-producing cells and structural abnormalities with a disorganized corticomedullary junction, and cortical and medullary cysts. This demonstrates that CBP and p300 are important for kidney development [146].

Simpson-Golabi-Behmel syndrome (SGBS; OMIM#312870) is an X-linked disorder in which patients display overgrowth, a distinct facial appearance, macroglossia, cardiac defects, dysplastic and cystic kidneys, hernias, supernumerary nipples, and various skeletal abnormalities, including polydactyly and syndactyly [147]. SGBS is due to mutations in the *glypican-3* (*GPC3*) gene which encodes a cell-surface glycoprotein [104]. Glypicans are a family of heparan sulfate proteoglycans that are linked to the cell surface through a glycosyl–phosphatidylinositol anchor. *Gpc3*-deficient mice reproduce clinical features observed in SGBS patients, including developmental overgrowth, perinatal death, cystic and dysplastic kidneys, and abnormal lung development [148]. Analysis of *Gpc3*-deficient mice has revealed that there is increased proliferation of the ureteric bud cells early in development and this is followed by selective degeneration of medullary collecting ducts that results in renal cystic dysplasia. Mechanistically, GPC3 inhibits renal branching morphogenesis by modulating BMP2-SMAD signaling [149].

Smith-Lemli-Opitz syndrome (SLOS; OMIM #270400) is an autosomal recessive syndrome caused by an inborn error of cholesterol metabolism from a mutation in the *DHCR7* gene on chromosome 11q13. The gene *DHCR7* encodes the enzyme 7-dehydrocholesterol reductase (7-DHC) that catalyzes the conversion of 7-DHC to cholesterol [105]. Metabolically, SLOS is characterized by reduced serum cholesterol levels and phenotypically by cognitive disability, facial dysmorphisms, syndactyly of the second and third toes, photosensitivity and holoprosencephaly in severe cases. Mild cases exhibit minimal physical abnormalities and near-normal intelligence [105]. Renal features include renal agenesis and dysplasia [105]. The molecular mechanisms leading to the renal developmental malformations found in SLOS patients are unknown, however, kidneys from *Dhcr7*$^{-/-}$ mice exhibit a defect in UB branching [150].

Townes-Brocks syndrome (TBS; OMIM #107480) is an autosomal dominant disorder caused by mutations in the *SALL1* gene. The *SALL1* gene is located on chromosome 16q12.1 and encodes a zinc finger transcription factor which is required for kidney development [106]. The syndrome is characterized by external ear anomalies, imperforate anus, preaxial polydactyly with triphalangeal thumbs, and cardiac anomalies [151]. The renal malformations reported in TBS consist of hypoplastic and/or dysplastic kidneys, renal agenesis, horseshoe kidney, multicystic dysplastic kidney, VUR, and PUV [106]. TBS occurs in 1 in 200,000 live births. De novo mutations in *SALL1* are observed in 50% of cases. Approximately 65% of patients have point mutations, and 5% deletions. The severity of the disease varies and is not correlated with the genotype. Mice deficient in *Sall1* die in the perinatal period with kidney agenesis [152]. *Sall1* is expressed in the metanephric mesenchyme surrounding the ureteric bud. Homozygous deletion of *Sall1* results in apoptosis of the adjacent metanephric mesenchyme and incomplete ureteric bud outgrowth which highlights the importance of the reciprocal signaling between these tissues for the formation of the metanephric kidney [152]. In addition, SALL1 is important for self-renewal and differentiation of nephron progenitor cells that are controlled, in part, by the transcription factor SIX2. Conditional deletion of *Sall1* in Six2-positive nephron progenitor cells results in severe depletion of this stem cell population and a marked reduction in nephron formation in the mouse. SALL1 regulates the balance between nephron progenitor cell self-renewal and differentiation by activating progenitor-related genes in SIX2-positive nephron progenitors and by repressing gene expression in SIX2-negative differentiating nascent nephrons [153].

Zellweger syndrome (ZWS; OMIM #214100), also known as cerebrohepatorenal syndrome, is an autosomal recessive disorder due to mutations in the pexin genes including *PEX1*, *PEX2*, *PEX3*, *PEX5*, *PEX6*, *PEX10*, *PEX12*, *PEX13*, *PEX16*, *PEX19*, or *PEX26* that are involved in peroxisome biogenesis. *PEX* genes are required to import protein and fatty acids from the cytosol into peroxisomes with subsequent enzymatic degradation. ZWS is characterized by craniofacial dysmorphisms (high forehead, widely separated cranial sutures, epicanthal folds, upward slant of the eyes), cataracts, pigmentary retinopathy, hepatomegaly with biliary dysgenesis, developmental delay, hypotonia and seizures [107]. Renal anomalies include glomerulocystic kidney disease and VUR [107].

Trisomies and CAKUT

Trisomy 13, 18, and 21 are relatively common causes of syndromic CAKUT. Trisomy 21 occurs in 1.5 in 1,000 births, while Trisomy 13 and 18 occur in 0.05 and 0.15 per 1,000 live births, respectively [154]. Approximately 5% of individuals with Trisomy 21 have CAKUT [155]. The most common forms of CAKUT in children with trisomies 13, 18, and 21 include hydronephrosis, horseshoe kidney, renal hypoplasia, duplex kidney/collecting system, cortical cysts, and cystic dysplasia. The mechanisms by which trisomies may cause CAKUT are unknown. Characteristic clinical features of Trisomy 21 (Down syndrome) include epicanthic folds, intellectual disability, congenital heart disease (atrioventricular septal defects, Tetralogy of Fallot), duodenal atresia, short stature, hypospadias, and cryptorchidism [156]. Trisomy 13 (Patau syndrome) is characterized by holoprosencephaly, microphthalmus, cleft lip and/or palate, congenital heart disease, and polydactyly. The major phenotypic features of Trisomy 18 (Edwards syndrome) include IUGR, hypertonia, congenital heart disease (ventricular septal defects and patent duct arteriosus), Meckel's diverticulum, and intestinal malrotation [157].

Environmental Factors that Predispose to Congenital Anomalies of the Kidney

From questionnaire data of 562 parents of children with CAKUT, maternal obesity and maternal diabetes were shown to be risk factors for CAKUT. Interestingly, maternal obesity was highly associated with duplex kidneys and VUR, while maternal diabetes was especially associated with posterior urethral valves [158]. Dart et al. demonstrated that pregestational diabetes was significantly associated with CAKUT (odds ratio, 1.67; 95% confidence interval, 1.14–2.46), which implies a 67% increased chance of CAKUT in the offspring of mothers with pregestational diabetes compared to the general population (8.3 vs. 5.0 per 1,000 births, respectively) [159]. In rat studies, maternal hyperglycemia and diabetes mellitus have also been linked to CAKUT [160].

Evidence derived from human and animal model studies demonstrates an important role for the intrauterine environment in the pathogenesis of CAKUT [161] (Table 5). Intrauterine growth restriction (IUGR), defined as fetal weight below the 10th percentile for gestational age, or low birth weight (<2500 g) strongly suggest that the in-utero environment is suboptimal. Maternal undernutrition is one of the most common causes of human IUGR [177]. In a variety of animal models, maternal dietary protein restriction results in decreased nephron number with impaired kidney function and hypertension [169]. Maternal protein restriction during pregnancy results in increased apoptosis of nephron progenitor cells and it alters gene expression in the developing kidney [170]. One specific mechanism by which maternal low protein diet may cause renal hypoplasia is by increasing fetal exposure to maternal glucocorticoids by downregulating placental production of the enzyme 11β-hydroxysteroid dehydrogenase type 2 which converts physiological glucocorticoids to inactive products. In animal models, high maternal glucocorticoid levels impair nephron formation in the fetal kidney. A maternal diet that is low in protein can also inhibit

Table 5 In utero environmental factors associated with CAKUT

Fetal exposure to	Renal phenotype	Reference(s)
ACE inhibitors or ARBs	Renal tubular dysgenesis (absence or poor differentiation of proximal tubules, retraction of glomerular tufts, thickening of arterial walls)	[162, 163]
Alcohol	Agenesis, ectopia/horseshoe, cystic dysplasia, hypoplasia, hydronephrosis/ureter	[164, 165]
Cocaine	Agenesis, hypoplasia, hydronephrosis/ureter	[166]
Dexamethasone/ Corticosterone	Hypoplasia	[167, 168]
Hyperglycemia	Agenesis, ectopic/horseshoe kidney, cystic/dysplasia, hypoplasia, hydronephrosis/ureter	[158, 159, 160]
Low protein diet	Hypoplasia	[169, 170]
Maternal obesity	Duplex kidneys, VUR	[158]
Thalidomide	Agenesis, ectopic/horseshoe kidney, cystic dysplasia, hypoplasia, hydronephrosis/ureter	[171, 172]
Uteroplacental insufficiency	Hypoplasia	[173]
Valproic acid	Hydronephrosis, ectopic kidney, MCDK	[174]
Vitamin A deficiency	Hypoplasia, hydronephrosis/ureter	[175, 176]

ACE Angiotensin-converting enzyme, *ARB* Angiotensin II AT1 receptor blocker fetal activation of the renin-angiotensinogen-system which results in impaired nephrogenesis [178–180]. Interestingly, when pregnant dams on a low protein diet receive retinoic acid, a metabolite of Vitamin A, kidney size and nephron number is normalized in the offspring [181]. Similarly, pregnant dams that are fed a Vitamin A deficient diet give birth to offspring with renal hypoplasia, a decrease in glomerular number, hydronephrosis and hydroureter [175, 176]. Indeed, retinoic acid is a potent morphogen during embryogenesis that signals through the retinoic acid receptors (RAR) to regulate apoptosis, differentiation, and cell fate specification. Deletion of *Rarα* and *Rarβ2* in mice causes renal hypoplasia and reduced expression of *Ret* in the ureteric bud [182].

Maternal uteroplacental insufficiency is another important cause of IUGR with secondary low nephron endowment in the fetus and is seen in women with hypertension, pre-eclampsia, and diabetes. The main cause of maternal uteroplacental insufficiency is vascular in which the spiral arteries that nourish the fetus fail to become low resistance, high flow vessels. Maternal uteroplacental insufficiency induced by incomplete bilateral uterine vessel ligation in animal models also has direct effects on fetal kidney development. In the rat model, uterine vessel ligation results in a decrease in glomerular number and renal hypoplasia in the offspring [173].

Several other environmental factors are risk factors for impaired nephrogenesis and CAKUT. In utero exposure to several medications, illicit drugs and alcohol have all been associated with renal dysplasia. Maternal use of renin-angiotensin system inhibitors such as ACE inhibitors, Angiotensin II receptor blockers, and direct renin inhibitors during pregnancy have been linked to an increased risk of fetopathy in humans. Most children manifest hyperechogenic and enlarged kidneys with proximal tubular dysplasia, thickening of arterial walls and multiple small cysts [162, 163].

Folic acid is required for cell division and cell maintenance and is an essential factor in DNA methylation, which is critical for epigenetic regulation of gene expression. Maternal supplementation with folate has been shown to decrease the risk of a neural tube defect in the developing fetus and there may also be benefit in prevention of CAKUT. Folic acid may reduce the incidence of urinary tract malformations [183]. Importantly, CAKUT phenotypes have been observed in infants exposed to folic acid antagonists in utero, such as carbamazepine, phenytoin, primidone, phenobarbital, or valproic acid, suggesting that folate is important for kidney and urinary tract development [174, 183].

Dexamethasone, a synthetic glucocorticoid that readily crosses the placental barrier, has also been shown to be detrimental to fetal kidney development. Animal studies have demonstrated that fetal dexamethasone exposure is linked to a reduction in nephron endowment and renal hypoplasia [167, 168]. Thalidomide is a drug with immunomodulatory and antiangiogenic characteristics that was originally prescribed for morning sickness and now is used to treat some cancers and skin conditions. Thalidomide use during pregnancy is teratogenic and induces severe limb deformities or phocomelia as well as CAKUT and renal hypoplasia [171, 172].

Maternal use of illicit drugs and alcohol are also risk factors for CAKUT. Children exposed to cocaine in utero have an increased risk of renal agenesis and hypoplasia [166]. While the mechanism is not clear, this could be due to cocaine-induced arterial vasoconstriction with uteroplacental insufficiency or maternal anorexia. Maternal alcohol consumption may cause Fetal Alcohol Syndrome which includes renal system anomalies [164, 165]. Here again, the mechanism is not known, but it may be secondary to the effect of alcohol on Vitamin A metabolism: retinol is metabolized to retinoic acid via alcohol dehydrogenase. Alcohol dehydrogenase may be inhibited in the setting of elevated levels of ethanol resulting in a deficiency of retinoic acid [184].

In summary, the underlying molecular mechanisms that cause CAKUT in response to a suboptimal in utero environment remain to be elucidated. However, there is strong animal data and some human data that reveals the importance of the in-utero environment for fetal development including the kidneys and urinary tracts. Further research in this area is essential to improve early diagnosis, prevention, and treatment of CAKUT and its associated comorbidities.

Abstracts

Because of the few effective treatments for many chronic kidney diseases, increasing consideration has been given to new regenerative therapies using stem cells. Recent advances in developmental biology and stem cell biology have led to the increased availability of renal stem/progenitor cells from multiple sources,

including their isolation from embryonic and adult kidneys, and to the generation of kidney lineage cells by the directed differentiation of pluripotent stem cells, such as embryonic stem cells (ESCs) and induced pluripotent stem cells (iPSCs), or by the cellular reprogramming of fully differentiated adult renal cells or across mature lineages. Cell therapies using renal stem/progenitor cells derived from adult and embryonic kidneys or differentiated from ESCs/iPSCs have been investigated in kidney disease models. The reconstruction of transplantable kidney organs is also being attempted using ESC/iPSC-derived kidney lineage cells. Cancer stem cells, which are thought to initiate and maintain malignant tumors, have been identified in renal cell carcinomas (RCC) and in Wilms' tumor (WT), the most common pediatric renal malignancy. The development of regenerative treatment using stem cells and their bioproducts and targeted therapies against renal cancer stem cells may open new avenues in renal medicine.

Introduction

Any pathologic process that leads to the loss of nephrons, which are the functional units of the kidney, may eventually cause decreased renal function, a process collectively termed chronic kidney disease (CKD) [1]. CKD gradually progresses to end-stage kidney disease (ESKD), and patients with ESKD only have two therapeutic options: renal transplantation and dialysis therapy. Renal transplantation is hampered by serious problems, including the shortage of donor organs, chronic use of immunosuppressive drugs, and chronic allograft failure. Dialysis therapy can substitute for a part of renal function, but eventually causes systemic complications. The lifespan of patients with renal transplants and on dialysis is also typically shortened compared to the general population for many reasons including cardiac disease, infections, neoplasia, etc. Also, the prevalence of CKD is increasing worldwide, which gives growing economic burden to health-care systems [1]. Since CKD represents a gradual loss of nephrons, substantial efforts have been made towards kidney regeneration using stem cells.

Stem cells have self-renewal capacity and differentiation potential into multiple cell types constituting the body. Progenitor cells that differentiate from stem cells are more developmentally committed to specific cell lineages. These two cell types are sometimes difficult to clearly distinguish and often equated. Stem cells are largely classified into two categories: tissue-specific or somatic stem cells and pluripotent stem cells (PSCs). Tissue-specific stem cells have been identified in most organs or tissues, including the kidney. They generally show relatively limited proliferation capability on culture dishes and limited differentiation potential into a restricted number of cell types constituting the original organ or tissue. In contrast, PSCs, such as embryonic stem cells (ESCs) [2] and induced pluripotent stem cells (iPSCs) [3, 4], have virtually unlimited replicative capacity and are theoretically able to give rise to any cell type in the body. Like other clinically useful cell types, vigorous efforts to differentiate kidney lineage cells from PSCs have been undertaken [5, 6].

An increasing number of reports have described the successful generation of desired cell types by manipulating core transcriptional factors to convert fully differentiated cells to a pluripotent state or from one fully differentiated cell type to another. This experimental strategy, termed cellular reprogramming, has been utilized to generate kidney lineage cells [5, 6].

In parallel to the above, a growing body of evidence has supported the idea that malignant tumors are initiated and maintained by cancer stem cells (CSCs), which share similar biologic properties with normal stem cells, showing the ability to self-renew as well as give rise to differentiated tissue cells [7, 8]. While most knowledge on CSCs had initially came from leukemia stem cells, cancer stem cell populations have also been identified from solid tumors, including adult and pediatric renal cancers [9]. The elucidation of the biological properties of CSCs would allow the development of therapies that target these malignant stem cell populations.

This chapter will summarize the current status of research on kidney regeneration using renal stem/progenitor cells isolated from embryonic or adult kidneys and kidney lineage cells generated by the directed differentiation of PSCs or by the cellular reprogramming of other cell types. Present knowledge on CSCs of kidney-related malignancies will also be described.

Embryonic Renal Stem/Progenitor Cells

Kidney Development

To understand the entity of embryonic renal stem/progenitor cells, this section starts by briefly summarizing mammalian kidney development (Fig. 1a; [10, 11]) (see ▶ Chap. 1, "Pre-natal Development of the Kidneys and Urinary Tract"). The kidneys are derived from an early embryonic germ layer, the intermediate mesoderm (IM; [12]), which is located between the lateral and paraxial mesoderm and derived from the primitive streak, which is the progenitor population for both the mesoderm and endoderm. A number of factors, such as WNT, bone morphogenetic proteins (BMPs), fibroblast growth factors (FGFs), and Nodal/activin and retinoic acid (RA) signals, contribute to the cell fate commitment of primitive streak or mesodermal lineage, including the IM. Especially, BMP signaling is the key morphogen regulating lateral-medial patterning of early mesoderm development. Low BMP induces IM, while high BMP induces lateral plate mesoderm, and the antagonism of BMP signals is required for paraxial mesoderm differentiation [13].

In vertebrates, the IM successively develops three types of kidneys: the pronephros, mesonephros, and metanephros. The three kidneys are similar in that they consist of a basic functional unit, the nephron, although the number of nephrons differs among the three. Mesonephros is the adult kidney of fish and amphibians, while metanephros is the functional kidney of adult amniotes, reptiles, birds, and mammals. The mammalian adult kidney, the metanephros, is formed by reciprocally inductive interactions between two embryonic precursor tissues derived from the IM: the metanephric mesenchyme (MM) and the ureteric bud (UB), a derivative of the nephric (Wolffian) duct. The UB induces the MM to differentiate into epithelialized nephrons and interstitium, while the MM directs the UB to elaborate the lower urinary tract from the collecting ducts through the renal pelvis and ureter to a part of the urinary bladder [14]. Taguchi et al. redefined the origin of the MM and elucidated the lineage commitment from the nascent mesoderm through the IM into either the MM or UB [15]. They demonstrated that the MM is generated from the posterior IM, which is distinct from the anterior UB precursor IM population.

A portion of MM cells condenses around the tips of the UB and differentiates into structures termed cap mesenchyme (CM). CM cells self-renew at the UB tips and give rise to various cell types comprising the nephron. Thus, the CM has been considered multipotent nephron stem/progenitor cells, which can self-renew and differentiate into different types of nephron epithelia [16]. Additionally, CM cells express a unique combination of transcription factors, such as the *Hox11* paralogs, *Osr1*, *Pax2*, *Eya1*, *Wt1*, *Six2*, *Sall1,* and *Cited1*, before UB induction.

The MM produces the secreted neurotrophin, glial cell line–derived neurotrophic factor (GDNF; [17]), which is a chemotactic factor for UB. GDNF drives the outgrowth of the UB from within the nephric duct and the extension of the UB toward the MM. The attracted UB in turn secretes WNT9b, which is the primary inducer for the MM [18] to induce the adjacent MM to condense around the UB tip, thereby forming the CM. Thereafter, WNT4 secreted from the induced CM epithelializes the CM itself in an autocrine fashion [19]. During the process of mesenchymal-epithelial transition (MET), the CM cells sequentially go through specific developmental stages including pre-tubular aggregates, renal vesicles,

and C- and S-shaped bodies, and then eventually differentiate into all nephron segments ranging from glomerular podocytes to distal renal tubules.

Among the key molecules involved in the process of kidney development, a homeodomain transcriptional factor, *Six2*, which serves as the most specific marker of CM cells, has been shown to play a central role in the regulation of renal progenitor CM cells, particularly on the ability of CM cells to continuously self-renew throughout nephrogenesis [16]. It was reported that FGF9 and FGF20 are required for the formation and maintenance of the CM progenitors, respectively [20]. MM survival in vitro also depends on FGF2 and BMP7 [21].

Upon completion of the kidney development, transcription factors expressed in the CM, including *Six2*, are no longer expressed and the embryonic nephron progenitors disappear, which leads to no formation of new nephrons. Embryonic renal progenitors do not exist in adult mice even after acute kidney injury (AKI) in ischemia-reperfusion (I/R) models, which were elegantly demonstrated by a lineage tracing study for *Six2* [22]. In contrast to mammals, which lose the renal progenitor pool around birth, a self-renewing nephron stem cell population has been shown to exist in the adult kidneys of lower organisms, such as zebrafish and drosophila, and to form new nephrons throughout adult life, contributing to regenerating nephrons de novo after injury [23, 24].

In addition to the *Six2*-expressing CM progenitors that give rise to several epithelial cell types constituting nephrons, such as glomerular podocytes and renal tubular epithelia, the developing kidney also contains progenitor cell types of other lineages. These include FOXD1(+) stromal progenitors in the MM, which differentiate into renal interstitial cells, mesangial cells, and vascular smooth muscle cells and pericytes in adult kidney [25–28]. Kobayashi et al. performed lineage tracing experiments and showed that the *Foxd1*-expressing cortical stroma represents a distinct multipotent self-renewing progenitor population that gives rise to the adult renal cell types described above throughout kidney organogenesis [28]. Interestingly, it was demonstrated that a small subset of FOXD1(+) stromal cells contributes to SIX2(+) nephron progenitors at early developmental stages, but thereafter a strict nephron and stromal lineage boundary is formed between the nephron and stromal progenitor compartments.

Most knowledge on kidney development has been obtained from genetic approaches with experimental animal models, including fish, frog, chick, and mice [5, 6, 10, 11]. Previous work has also examined embryonic kidneys in human and nonhuman primates, such as rhesus monkey. Humans, nonhuman primates, and mice share several molecules and corresponding spatial expression patterns that act as developmental markers, although major

[13], (**d**) and (**e**)–(**i**) are adapted from Mae et al. [57, 58], respectively) differences have been found in the temporal patterns of kidney development. Nephrogenesis starts in human and nonhuman primates at the end of the first trimester and continues throughout the mid-third trimester with a term of 165 ± 10 days, while mouse nephrogenesis begins in mid-gestation and completes postnatally with a term of 20 days [5, 6, 10, 11].

Identification of Embryonic Renal Stem/Progenitor Cells

As described above, the metanephric kidney contains several stem/progenitor cell populations required for the formation of a fully functional kidney. This property has also been demonstrated by the transplantation of whole embryonic kidney rudiments into extrarenal space of host animals. Hammerman et al. [29] and Dekel et al. [30, 31] demonstrated the formation of vascularized renal tissues from transplanted metanephroi inside the rodent body. Notably, when mouse, rat, porcine, or even human early-gestational metanephroi are transplanted into the kidney subcapsular space or the abdominal cavity of immunodeficient mice, they survive, grow, undergo complete nephrogenesis, and form functional organs that are able to produce dilute urine by integrating with the host vasculature and forming vascularized glomeruli comprised of donor-host connections [31]. These seminal studies paved the way for transplantation studies using fetal-like organoid kidney tissue derived from PSCs to achieve host-derived vascularization and maturation [32].

In addition to the transplantation of whole metanephric rudiments, Kim et al. reported that transplantation of a heterogeneous population of dissociated embryonic day (E) 14.5 and E17.5 rat fetal kidney cells under the renal capsule of a 5/6 nephrectomy kidney injury model resulted in the formation of renal structures and improved renal functions [33].

The selection or isolation of specific lineage of progenitor cells included in embryonic kidneys have also been performed either by sorting based on the expression of specific markers or by selective in vitro assays. By creating a clonogenic assay system using *Wnt4*, an epithelializing factor for MM in embryonic development, Osafune et al. demonstrated that the MM contains multipotent nephron progenitor cells (NPCs) that can give rise to several kinds of epithelial cells, such as glomerular podocytes and the epithelia of the proximal and distal renal tubules and Henle's loop [34]. The progenitor cells are contained only in the cell population that strongly expresses *Sall1*, a zinc finger transcription factor that is essential for kidney development and can reconstitute three-dimensional (3D) kidney structures in an organ culture setting that contain glomeruli- and tubule-like components. This clonogenic assay, however, has not yet been applied to human fetal kidney and cannot be used to expand undifferentiated NPCs.

Other approaches to isolate progenitor cells include culturing them as spheres based on the ability of progenitor cells to grow in low-attachment conditions. Lusis et al. established nephrospheres from murine embryonic kidneys, which robustly propagated in vitro, but displayed limited nephrogenic capacity [35]. Recently, several groups have developed in vitro expansion culture methods for mouse and human embryonic NPCs [36–38]. In particular, Li et al. expanded SIX2(+) mouse NPCs over 17 months with more than 110 passages and NGFR(+)EPCAM(+) human NPCs from gestational week (GW)11 human fetal kidneys more than 7 months with 50 passages by using combinations of growth factors and chemical compounds and 3D floating cell aggregation cultures [38].

Methods to prospectively isolate fetal kidney progenitor cells using surrogate cell surface markers of intracellular renal transcription factor expression have also been used to potentially supply an unlimited source of nephron progenitors; these in turn could be used to regenerate damaged epithelial cells within the nephron. Using a previously reported isolation method for the putative progenitor population in adult kidney, Lazzeri et al. isolated a similar CD24(+)CD133(+) cell population from human fetal kidneys [39]. They reported that the CD24(+)CD133(+) population represents 35–50% of early embryonic kidney cells, but gradually decreases in proportion and becomes restricted to the urinary pole of the Bowman's capsule with age. This population may possibly persist into adulthood as progenitors. Importantly, when isolated and injected into immunodeficient mice with acute kidney injury (AKI) by glycerol-induced rhabdomyolysis, CD24(+)CD133(+) cells regenerated different portions of the nephron, reduced tissue necrosis and fibrosis, and significantly improved renal function without tumor formation [39]. The authors concluded that CD24(+)CD133(+) cells represent a subset of multipotent early embryonic progenitors that persist in human kidneys.

A group headed by Benjamin Dekel employed a unique stepwise strategy in order to identify cell surface markers for isolation of human embryonic renal stem/progenitor cells. To identify candidate markers that are highly expressed in renal progenitor-rich tissues compared with differentiated renal tissues, the group compared the global gene expression in human embryonic kidney, human adult kidney, and Wilms' tumor (WT) by oligonucleotide microarray [40]. Since WT specimens frequently harbor cells that have differentiated into renal tubular epithelia or stroma, in addition to uninduced metanephric blastema, the group serially propagated WT xenografts in mice to purify blastema tissues at the expense of differentiated elements for the analysis. They then pinpointed molecular markers jointly overexpressed in the human embryonic kidney and WT in the microarrays. This analysis uncovered a large number of candidate genes marking renal "stemness," including nephron progenitor transcription factor markers (e.g., *SIX1, SIX2*, *CITED1, EYA1, SALL1*, and *PAX2*) and cell surface markers (*NCAM1*, *PSA-NCAM*, *FZD7*, *FZD2*, *DLK1*, *ITGα8, ACVRIIb*, and *NTRK2*) [40, 41]. The group sought to find the best candidate surface molecule by identifying those that were exclusively expressed in undifferentiated cortical areas of embryonic kidneys; furthermore, they sought to find a surface protein that marked cells that had characteristics of tissue-specific stem cells including those that expressed renal progenitor genes and had self-renewal capacity, colony formation capability, and renal differentiation potential [42]. They eventually identified NCAM1 (CD56) as a potential surface marker for human embryonic renal stem/progenitors that fulfills all these criteria [41, 43].

NCAM1(+) cells isolated from human embryonic kidney cells and cultured in serum-free medium showed significant enrichment of nephron progenitor genes, such as *SIX2*, *OSR1*, *PAX2, SALL1, CITED1*, and *WT1*, compared to NCAM1 (−) cells [43]. The renal differentiation potential of NCAM1(+) cells was demonstrated using a chorioallantoic membrane (CAM) transplantation model, in which cells are grafted onto a highly vascularized niche, rich in developmental cues [44]. The model showed that NCAM1(+) cells generated well-developed epithelial tubular structures expressing markers for the proximal tubule, distal tubule, and loop of Henle. Harari-Steinberg et al. evaluated the regenerative potential of the NCAM1(+) population in a 5/6 nephrectomy CKD model; they demonstrated that NCAM1(+) human embryonic nephron progenitors engrafted and integrated into diseased murine kidneys after transplantation, and that consecutive intraparenchymal administration halted the progression of renal disease and improved creatinine clearance over 12 weeks of treatment [43]. Therefore, it was concluded that NCAM1(+) human nephron progenitors are a pool of mitotically competent yet strongly nephron-generating biased cells. Importantly, the NCAM1(+) cells sorted from human fetal kidney and cultured in serum free media encompassed both SIX2(+) and SIX2(−) cells. Therefore, for enrichment of the SIX2(+) progenitor cell fraction, additional surface markers were required as well as defined media that favors expansion of the SIX2(+) population. In addition, to optimize culture conditions for human cells, the group used media developed initially by the Oxburgh group [36] for expansion of mouse nephron progenitors [45]. It also became apparent that to exclude any renal epithelial differentiation, a combination of positive and negative markers should be employed for prospective isolation [45, 46]. Accordingly, utilizing three markers NCAM1, EpCAM, and CD133 allowed prospective isolation of progenitors [NCAM1(+)EpCAM(−)(CD133(−)] from their differentiating epithelial progeny that arise in development. As such, isolation of early differentiating fetal kidney renal progenitors may also represent a potential regenerative strategy (e.g., by sorting NCAM1(+) EpCAM(dim) cells) [46].

Although the embryonic kidney progenitors represent a promising cell source for renal regeneration, the ethical problems arising from the use of human embryos as well as the allogeneic nature of primary human cells limit their use. In this regard it remains to be determined whether the bio-marker system Dekel and colleagues discovered for prospective isolation of human fetal kidney progenitor cells will be identical in PSC-derived kidney organoids. Therefore, efforts to identify a nephrogenic cell population in adult kidneys or to generate cells equivalent to embryonic renal progenitors from autologous stem cells, such as iPSCs, are required to accelerate research towards the clinical application of transplantation therapy for kidney diseases.

Generation of Kidney Lineage Cells from PSCs

PSCs

PSCs can be broken down into two major types, ESCs [2] and iPSCs [3, 4]. ESCs are derived from the inner cell mass of fertilized eggs in mammals [2], while iPSCs are generated from transducing somatic cells with reprogramming factors, such as the combination of OCT4, SOX2, KLF4, and c-MYC that are found in ESCs [3, 4]. Moreover, regenerative medicine research has explored in vivo transplantation of organ-specific cell types generated from PSCs in vitro. iPSCs are appealing because they offer similar features of ESCs while avoiding the ethical problems related to the use of human fertilized eggs. Further, unlike ESCs, they also can be made from the patients' own cells, which would allow for autologous transplantations, to avoid the risk of immune rejection after the transplantation [47].

Despite the potential of iPSCs for medicine, they have the risk of developing into cancers. iPSCs were originally derived using genome-integrating vectors, such as retroviral and lentiviral vectors, to introduce the reprogramming factors into somatic cells, which could lead to cancer [3, 4]. Although several alternative iPSC derivation methods have been reported to solve the mutagenesis problem, most are less efficient and reproducible than the original methods. Okita et al. developed a safe and efficient system that eliminates the integration of reprogramming factors into the genome of the somatic cells by using episomal vectors encoding OCT4, SOX2, KLF4, L-MYC, LIN28, and a shRNA for TP53 [47]. This method leads to iPSC formation from any cell type with equivalent efficiency to the original methods with less risk of neoplasia.

Clinical trials of cell therapy using human ESC-derived cell types have happened for spinal cord injury, retinal degenerative disorders, type 1 diabetes, and heart failure [48]. The first clinical trial included transplantation of human iPSC-derived retinal pigmented epithelial sheets into a patient suffering from age-related macular degeneration [47]. Thereafter, cell therapies using iPSCs have been used for clinical trials for several other intractable disorders including Parkinson's disease, heart failure, corneal diseases, and thrombocytopenia. In parallel, clinical trials using drug compounds screened for effectiveness in iPSCs derived from patients with hereditary disorders, such as fibrodysplasia ossificans progressiva (FOP), amyotrophic lateral sclerosis (ALS), and Alzheimer disease, are ongoing [47].

Directed Differentiation of PSCs into Kidney Lineage Cells

Although PSCs in kidney research was originally slow compared to use with other organs, substantial progress has recently been made. By recapitulating the signals involved in the differentiation steps during embryonic development, protocols have been used to differentiate PSCs into kidney lineages (Fig. 1a). Kim and Dressler reported that embryoid bodies (EBs) formed from mouse ESCs can be induced into IM in vitro by a combined treatment of RA, activin A, and BMP7 [49]. These EBs developed renal tubule-like structures in coculture with embryonic spinal cord, which is a classical inducer of the MM; furthermore, the induced cells integrated into the proximal tubules when microinjected into E12.5 mouse kidney organ cultures. Taguchi et al. demonstrated that

NPCs are derived from the posterior mesoderm and identified the optimal combination of factors that drive formation of NPCs [15]. They established a stepwise differentiation protocol from mouse ESCs to the epiblast, nascent mesoderm, posterior nascent mesoderm, posterior IM, and ultimately NPCs; these NPCs were capable of forming 3D nephron structures containing numerous glomeruli and renal tubules by coculture with embryonic spinal cords.

Over the last decade, many studies have achieved the directed differentiation of kidney lineages from human PSCs [5, 6]. Mae et al. generated OSR1-GFP knockin reporter human iPSC lines to monitor the expression of OSR1; the group demonstrated that treatment with activin A, BMP7, and CHIR99021 in two-dimensional (2D) monolayer cultures induced the cells into OSR1(+) cells at over 90% efficiency [50]. These induced IM cells could further differentiate into adult renal cell types, such as glomerular podocytes and renal tubular cells, and form 3D renal tubular structures in vitro. Lam et al. also established a simple, rapid, and efficient 2D differentiation protocol from human PSCs into IM with 70–80% efficiency [51]. These IM cells could differentiate into cells expressing NPC markers and gave rise to apically ciliated proximal tubular structures.

Subsequent to the studies with OSR1 reporter lines, the selective induction of NPCs through posterior IM was reported. Taguchi et al. modified the differentiation protocol used to induce mouse ESCs into NPCs (described above) to human iPSC differentiation cultures by changing the early steps for mesoderm induction and the culture periods of the later steps [15]. Although the induction efficiency of NPCs was only 40%, the induced human NPCs formed 3D nephron structures (nephron organoids) that consisted of glomeruli and renal tubules upon coculture with mouse embryonic spinal cords. Takasato et al. reported that prolonged CHIR99021 treatment shifts the fate of human PSCs from anterior IM to posterior IM and that the mixture of these two IM populations spontaneously form self-organized kidney organoids containing multiple kidney cell types, such as glomeruli, renal tubules, collecting ducts, and interstitial and vascular cells [52]. Morizane et al. later reported a simple and efficient 2D culture to differentiate human PSCs into NPCs at around 90% efficiency [53]. More recently, Tsujimoto et al. established a six-step differentiation method that induces multiple human iPSC lines through the primitive steak and posterior IM into NPCs with nephrogenic potential at around 90% efficiency, by more accurately reproducing the developmental process of NPCs (Fig. 1b, c) [13]. By screening the effects of various growth factors in the differentiation culture from the mouse embryonic NPCs to glomerular podocytes, Yoshimura et al. succeeded in generating podocytes from human iPSCs and NPCs at more than 90% efficiency [54]. The induced podocytes exhibited morphologic features, gene expression profiles, and functional responsiveness to drug-induced injury that were comparable to those of adult human primary podocytes.

To induce UB lineages, Xia et al. generated UB progenitor IM cells from human iPSCs that contributed to mouse UB tissues upon coculture with dissociated mouse metanephric cells in organ cultures [55]. Two other groups later reported the directed differentiation of UB-like tissues from PSCs [56, 57]. Taguchi and Nishinakamura induced both mouse ESCs and human iPSCs through anterior IM and nephric ducts (NDs) into 3D UB-like tissues using EBs [56]. However, the differentiation efficiency of the ND epithelia was low (around 40%), requiring purification of the epithelia by flow cytometry sorting before further differentiation into UB-like tissues. Conversely, Mae et al. succeeded in efficiently generating ND epithelia at more than 70% of induction rate by inducing human iPSCs through anterior IM in a 2D monolayer differentiation protocol that avoided the purification step when generating UB-like tissues (Fig. 1d, e) [57]. However, the UB-like tissues generated with either method showed limited capacity for branching morphogenesis. More recently, Mae et al. modified their directed differentiation method to generate UB organoids [58]. They used cultures with low-concentration Matrigel to generate UB organoids that exhibited apicobasal polarity, tubular lumens, and repeated branching potential (Fig. 1f–h). Moreover, the separated tip regions from the organoids were able to continue to repeatedly branch and reconstituted UB organoids. The group repeated the separation process three to four times, allowing each organoid tip to branch four to five times, indicating that each tip had the capacity to branch at least 20 times like their counterparts in human fetal kidneys. Moreover, the group succeeded in further inducing human iPSC-derived UB organoids into collecting duct progenitors expressing AQP2, which corresponded to their counterparts in GW7 embryonic kidneys as evaluated by comparative gene expression (Fig. 1i) [58].

In summary, human PSCs can be differentiated into both NPCs and UB tissues through the IM; furthermore, nephron structures containing glomeruli and renal tubules and collecting duct tissues can be formed in vitro from the induced progenitors.

Kidney Reconstruction

As described above, nephron organoids containing glomeruli and renal tubules and collecting duct organoids can be generated from human PSC-derived NPCs [13, 15, 52, 53] and UB cells [58], respectively. Upon transplantation into the subcapsular or subcutaneous space of immunodeficient mouse kidneys, glomeruli in the nephron organoids vascularized and connected to the host's blood stream [32, 59–61]. The transplanted glomeruli formed slit diaphragm-like structures consisting of the basement membrane, fenestrated endothelial cells, and podocyte foot processes [59]. The transplanted tubular epithelia also exhibited polarization and segmental specialization, suggesting that functional vascularization facilitates glomerular and tubular maturation in vivo. Furthermore, in vivo imaging showed that glomeruli in the transplanted human PSC-derived nephron organoids displayed dextran and albumin size selectivity across their glomerular filtration barrier, and proximal tubules reabsorbed dextran, indicating functional filtration of the transplanted human glomeruli [60].

Taguchi and Nishinakamura combined NPCs and UB tissues differentiated from mouse ESCs and stromal progenitors removed from mouse embryonic kidneys in vitro, which then formed renal organoids with glomeruli, renal tubules, and collecting ducts that were interconnected [56]. Tsujimoto et al. generated human kidney organoids by combining human iPSC-derived NPCs and UB cells in vitro, leading to interconnections between NPC-derived glomeruli and renal tubules and UB-derived collecting ducts (Fig. 1j) [13]. Upon transplantation of these organoids into the renal subcapsular space of immunodeficient mice, connections between human iPSC-derived glomeruli and the host's blood stream were observed by intravital multiphoton microscopy imaging (Fig. 1k, l). Limitations however are that these kidney-like structures generated from human PSCs were very small in size at only several millimeters in diameter. Thus, generation of larger kidney tissues are required for clinically relevant use in human kidney transplantation.

Towards this goal, an experimental strategy called interspecific blastocyst complementation has been investigated, in which wild-type PSCs are injected into the blastocysts of animals genetically modified not to develop the target organs of interest and thus the organs are formed entirely from the injected PSCs. Nakauchi's group demonstrated that wild-type mouse and rat PSCs injected into PDX1 (−/−) (pancreatogenesis-disabled) rat and mouse blastocysts, respectively, generated an almost entire PSC-derived pancreas interspecifically [62]. This approach has subsequently been applied to generate whole kidneys. Usui et al. injected wild-type mouse ESCs into the blastocysts of *Sall1* knockout mice and confirmed that kidneys developed with MM-derived glomeruli and renal tubules that originated from the injected ESCs [63]. However, as expected, the UB-derived collecting ducts and lower urinary tract and vasculature were derived from the host mouse. Goto et al. recently succeeded in generating mouse PSC-derived MM in anephric SALL1 (−/−) mutant rat by interspecific blastocyst complementation [64].

Yamanaka et al. utilized the developmental organ niche of later stage fetuses of different species for kidney organ regeneration [65]. They developed a combination system by which donor NPCs are precisely injected into the nephrogenic zone of Six2-Cre-inducible diphtheria toxin (DT) receptor transgenic mice, in which native

NPCs are conditionally eliminated by DT injection. They succeeded in removing Six2(+) NPCs in the nephrogenic niche of the host mice and replacing them with transplanted wild-type mouse NPCs in ex vivo organ cultures. The transplanted NPCs developed into glomeruli and renal tubules that connected to host collecting ducts and further vascularized following transplantation. Furthermore, they interspecifically generated rat nephrons by replacing host mouse NPCs [65]. Later, the group developed a cell transplantation method through which mouse NPCs were accurately transplanted into the fetal kidney development area of E13–14 mouse embryos in utero [66]. The transplanted NPCs contributed to the chimeric CM of donor and host NPCs that was connected to the host UB. This experimental approach also generated chimeric kidneys in which MM lineage cells originate from donor PSCs while other kidney constituents are from the host animals. Further studies may develop strategies to replace both MM and UB lineage cells with donor PSC-derived cells to generate kidneys that are entirely from PSCs.

Cell Therapies Using Human PSC-Derived Kidney Progenitors

In parallel with reconstruction of the kidney organs, human iPSC-derived kidney progenitors have been used as cell therapies to treat kidney diseases [67, 68]. Imberti et al. generated and injected NPC-like progenitors from human iPSCs into the tail vein of immunodeficient mice with AKI induced by cisplatin administration [67]. This therapy significantly suppressed the elevation of blood urea nitrogen (BUN) and the histological injury typical of AKI, such as tubular necrosis and cast formation in the host mice. Because the injected progenitors only integrated into and contributed to small portions of the recipient's renal tubules, the therapeutic effects might be attributable to the paracrine effects by humoral factors secreted from the progenitors.

Toyohara et al. generated OSR1-GFP/SIX2-tdTomato double knockin reporter human iPSC lines and induced the cells into OSR1(+)SIX2(+) NPC-like progenitors [68]. They transplanted the OSR1(+)SIX2(+) progenitors after sorting by flow cytometry into the renal subcapsular space of immunodeficient mice with AKI induced by I/R injury with unilateral nephrectomy. Increased BUN and serum creatinine values of the host mice were significantly suppressed compared with saline injection or transplantation of undifferentiated human iPSCs (Fig. 2a). The therapy also significantly ameliorated the histological injury patterns of AKI, including tubular necrosis, urinary casts, and interstitial fibrosis (Fig. 2b). The transplanted progenitors had not integrated into host kidney parenchyma, however, suggesting again that the therapeutic benefits were mainly produced by paracrine factors secreted from the progenitors. Indeed, the study also showed that the progenitors secreted multiple known renal trophic factors, such as angiopoietin 1, vascular endothelial growth factor (VEGF) A, and hepatocyte growth factor (HGF) [68].

The therapeutic benefits of mouse embryonic NPCs with AKI were also confirmed recently. Li et al. showed that the renal subcapusular transplantation of mouse embryonic NPCs expanded in vitro improved survival rate and ameliorated kidney injury in cisplatin-induced AKI model mice both biochemically and histologically. The transplanted NPCs did not integrate into the parenchyma of the host mouse kidney, suggesting once more that paracrine factors likely produce the beneficial effects [38].

Embryonic Renal Stem/Progenitor Cells Reprogrammed from Adult Renal Cells

The success of direct cellular reprogramming from one terminally differentiated cell type into another has been shown in several cell types including kidney lineage cells [5, 6]. In these reports, transduction using a combination of three or more transcription factors was essential for differentiation into the target cell type. Kaminski et al. converted the fibroblasts to an induced renal epithelial cell (iREC) via the combined expression of *Emx2*, *Hnf1b*, *Hnf4a*, and *Pax8* [69]. Hendry et al. reported that the forced expression of six transcription factors

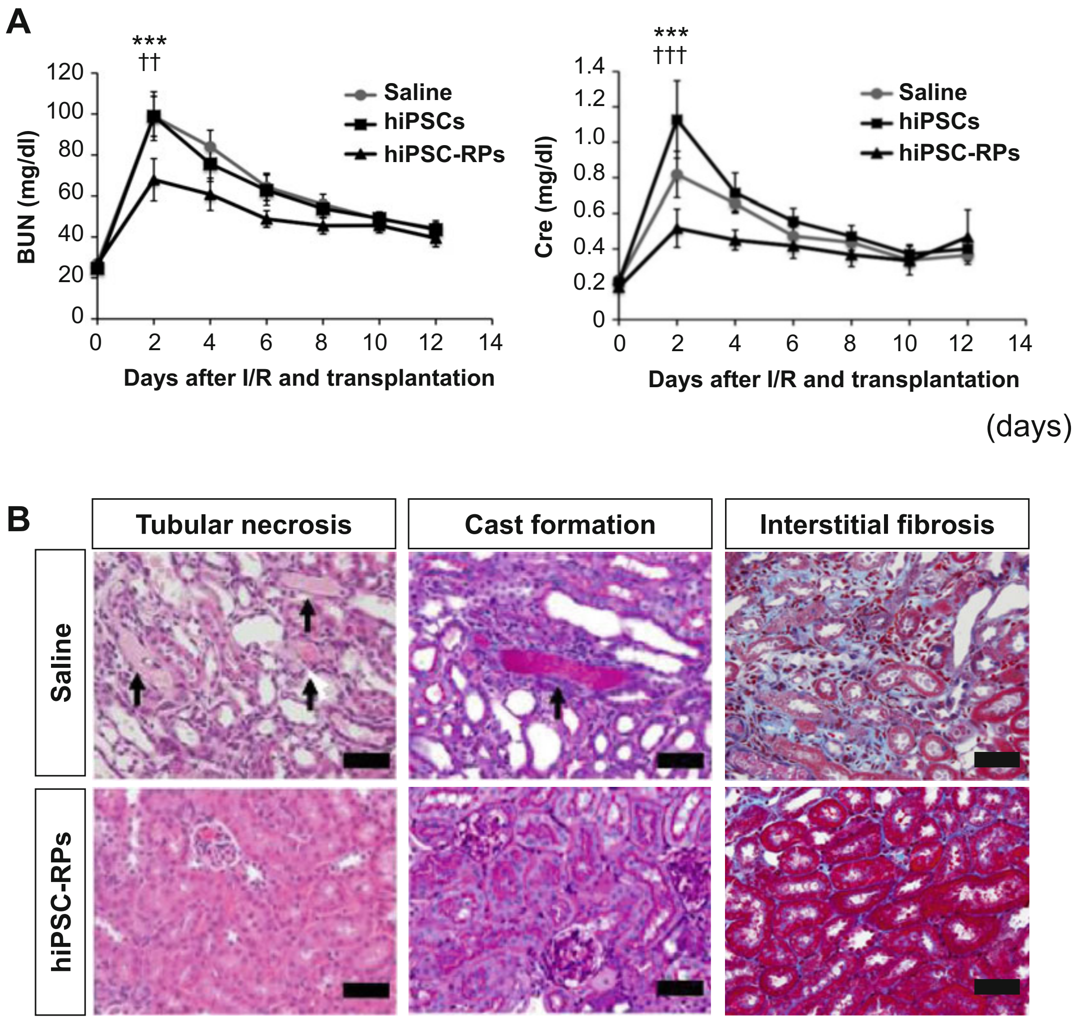

Fig. 2 Cell therapy using human iPSC-derived kidney progenitors. (**a**) Time course analysis of blood urea nitrogen (BUN) and serum creatinine (Cre) values in acute kidney injury (AKI) model mice induced by ischemia-reperfusion (I/R) injury that received saline injection (grey circles) or the renal subcapsular transplantation of undifferentiated human iPSCs (hiPSCs; black squares) or of human iPSC-derived renal progenitors (hiPSC-RPs; black triangles). ***, $p < 0.001$ versus saline; ††, $p < 0.01$ versus hiPSCs; †††, $p < 0.001$ versus hiPSCs. (*SIX1*, *SIX2*, *OSR1*, *EYA1*, *HOXA11*, and *SNAI2*) or even just three (*SIX1*, *OSR1*, and *SNAIL2*) drove reprogramming to an NPC-like fate [70, 71]. Hiratsuka et al. directly introduced synthetic mRNAs encoding transcription factors into human PSCs to generate NPC-like cells (*FIGLA*, *PITX2*, *ASCL1*, and *TFAP2C*) or to become pretubular aggregates (*HNF1A*, *GATA3*, *GATA1*, and *EMX2*; [72]).

In addition, Omer et al. showed that treating mature human adult kidney epithelial cells with valproic acid, a histone deacetylase (HDAC) inhibitor, results in significant activation of embryonic renal progenitor genes, such as SIX2, OSR1, SALL1, NCAM, and PSA-NCAM [73]. However, the same treatment inhibits cell dedifferentiation towards a more replicative mesenchymal state, which is required for the clonogenic expansion and acquisition of stem cell characteristics. The authors are now utilizing single pluripotent molecules such as OCT4 to achieve a tissue progenitor state in cultures of human adult kidney to allow both clonogenic self-renewal and preservation of renal potential over many generations.

In summary, research on direct cellular reprogramming into renal cell types is still nascent, and further studies will be required to establish methods for generating renal stem/progenitor cells that are devoid for any risk of malignant transformation.

Adult Renal Stem/Progenitor Cells

Stem Cells of Extrarenal Sources

Two types of tissue-specific stem cells included in bone marrow have been reported to contribute to renal tissues: hematopoietic stem cells [74] and mesenchymal stem/stromal cells (MSCs: [75]). While originally hypothesized to be circulating from bone marrow and responsible for the homeostasis, regeneration and repair of adult mesenchymal tissues, MSCs are now considered a subpopulation of perivascular cells or pericytes that reside in almost all tissues of our body. MSCs are thought to be recruited from their perivascular niche to sites of tissue injury, where they establish a regenerative microenvironment to facilitate tissue regeneration by secreting various bioactive molecules [76].

Early reports described that bone marrow–derived cells can differentiate into multiple somatic cell types including renal tubular cells, indicating the "plasticity" of stem cells to transdifferentiate into cells belonging to other organs, including organs derived from other germ layers [77]. However, since those reports, spontaneous cell fusion was demonstrated between mouse bone marrow cells and mouse ESCs [78], suggesting that at least part of the transdifferentiation of bone marrow stem cells occurs by spontaneous cell fusion between transplanted bone marrow cells and recipient host tissue cells.

The injection of bone marrow–derived cells, especially MSCs, has repeatedly been shown to improve renal function in AKI induced by toxins (cisplatin and glycerol) or I/R injury [79]. Similar beneficial effects on renal function may be obtained by administering growth factors, such as granulocyte colony-forming factor (G-CSF), granulocyte/monocyte colony-forming factor (GM-CSF), monocyte colony-forming factor (M-CSF), or stem cell factor, to mobilize a patient's bone marrow cells. Several studies (except for one) have indicated such administration improves renal function.

It is currently believed that any contribution made by nonrenal stem cells, including MSCs, to the regeneration of renal tissues is not due to differentiation and integration into tubular cells in vivo. Humphreys et al. elegantly demonstrated this concept in mice by using lineage tracing experiments [22]. They demonstrated that the cells responsible for tubular regeneration after AKI induced by I/R injury originate from remaining renal tubular cells, thereby excluding any possible contribution of extrarenal stem cells to regenerating kidney. Instead, MSCs seem to contribute to kidney repair after damage by secreting trophic factors, such as VEGF, bFGF, monocyte chemoattractant protein-1 (MCP-1), HGF and insulin-like growth factor 1 (IGF1), and immunomodulators, such as TGF-β and prostaglandin E2 (PGE2). While MSCs have consistently been shown to exert renoprotective effects in animal models of AKI, the therapeutic effectiveness of MSCs in preventing CKD is controversial [79].

A novel strategy mixing extrarenal and renal tubule-forming cells has recently been suggested as a potential route to harness the relative advantages of each cell type. Pleniceanu et al. have generated a cellular mix for regeneration; they combined human vessel-forming cells, comprised of endothelial colony-forming cells (ECFCs) and MSCs, with kidney tubule-forming cells resulting in 3D human kidney spheroids termed nephrospheres. Transplantation of nephrospheres into the subcapsular space or directly into the kidneys of mice resulted in the formation of both renal tubules and patent donor-derived vessels, which connected to the host vasculature and carried host RBCs [80]. This strategy has the benefit of generating renal parenchymatic units (i.e., tubules), as well as new vessels, which together have potential in improving oxygenation to the hypoxic CKD kidney and alleviating tissue fibrosis.

Sources of Adult Renal Cells Responsible for In Vivo Regeneration

As mentioned above, the lineage tracing experiments done by Humphreys et al. demonstrated that the cells responsible for tubular regeneration after I/R injury are of tubular origin, not transplanted extrarenal cells [22]. The study also demonstrated that adult mouse kidneys do not contain embryonic NPC-like cells expressing *Six2*, and that the reactivation of this cell population does not occur even after ischemic damage. This indicated that regeneration of new tubular cells originates from intrinsic epithelial cells in adult kidneys. However, it remains unclear whether these regenerating cells are epithelial progenitors with more restricted differentiation potential than Six2(+) embryonic progenitors or are fully differentiated tubular cells that can expand after ischemic damage.

Kusaba et al. answered this question by genetically labeling fully differentiated proximal tubule cells using mice in which a CreER(T2) cassette was knocked into the sodium-dependent inorganic phosphate transporter SLC34a1 locus; they then examined the cells' contributions to regenerating renal epithelia after ischemic injury [81]. After injury, all tubular cells remained labeled, indicating that new regenerating tubular cells originated from the proliferation of surviving differentiated tubular epithelia. Interestingly, injury to labeled proximal tubule epithelia induced a certain degree of dedifferentiation as manifested by the marker expression of putative epithelial stem cells, such as CD24, CD133, vimentin, and kidney injury molecule-1 (KIM-1). Their results provided no evidence for an intratubular stem cell population, but rather indicated that terminally differentiated tubular epithelia dedifferentiate to some extent by reexpressing some stem cell markers to then repair the damaged tubules [81].

Consistent with these results, Vogetseder et al. investigated the contribution of stem cells to the growth of proximal tubular S3 segments in healthy rats by administering thymidine analog and bromodeoxyuridine (BrdU) and examining expression of cell cycle markers, such as the G(1)-phase marker cyclin D1 [82, 83]. They found that cycling and non-cycling tubular cells have the same degree of differentiation, that the transient amplifying cells, usually thought to be the descendent of stem cells, were absent, and that most tubular cells in the S3 segment divided or entered the cell cycle in response to a proliferative stimulus. These results confirmed that tubular cells originate from differentiated tubular cells and not from stem cells [82]. The group also demonstrated that ~40% of S3 tubular cells are in G(1) phase and that a strong mitotic stimulus shortens the period of quiescence following cell division; together, this suggested that the capacity of the proximal tubule to rapidly recruit cells to divide depends on a large reserve pool of cells in G(1) cells with capacity to shorten the quiescence period [83].

Similar results were demonstrated by Berger et al. using the transgenic PEC (parietal epithelial cell)-reverse-tetracycline trans-activator (rtTA) mouse, which allowed cell fate tracing of regenerating proximal tubular cells [84]. They found that tubular regeneration after I/R injury occurred from surviving tubular cells rather than from fixed progenitor cells. Together, these aforementioned studies strongly suggest that no resident pool of stem cells exist to regenerate lost tubular cells after AKI, but rather surviving tubular cells proliferate to repair the injury.

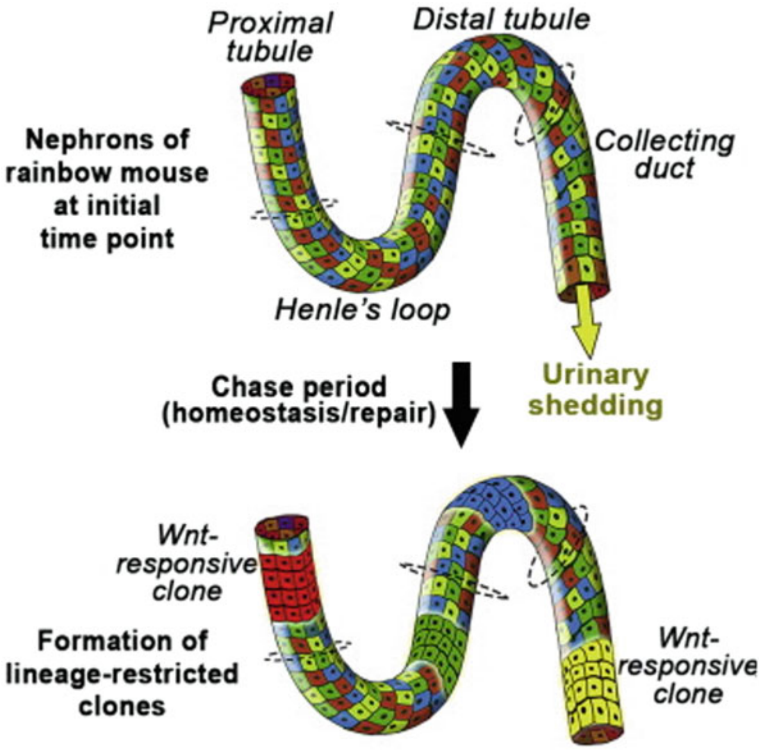
Rinkevich and Dekel examined the mechanisms and magnitude by which the mammalian kidney generates and maintains tubular cells by using multicolored "rainbow" mice, in which every cell is randomly marked by one of four fluorescent colors, allowing long-term lineage tracing and clonal analysis of new tubular cells [85]. They found that the adult mammalian kidney undergoes constant cell replacement during homeostasis and after injury by clonal expansion of lineage – or fate – restricted precursor cells that give rise only to cells of the same nephron segments they reside in.

Wnt activation in single cells could initiate the largest clones. They concluded that adult nephron epithelial cells can function as uni-potentional progenitors continuously maintaining and preserving all segments of the mouse kidney throughout life by clonal proliferation (Fig. 3). Interestingly, the same lineage boundaries within the kidney were found to apply to in vitro cultured cells. For instance, Cohen-Zontag et al. recently identified single-cell-derived clones via transcriptomics, and demonstrated ex vivo human kidney cell growth in segment-specific clones harboring either proximal or distal identity, as opposed to mixed clones [86]. This confirms both the lack of multipotent stem cells in the adult mammalian kidney and existence of clear sublineage boundaries in its in vitro equivalent. Notably, similar findings have been demonstrated by Pleniceanu et al. with respect to nonepithelial lineages in the kidney [80]. In order to generate both epithelial tubules and human vessels upon injection into the murine renal subcapsules, three cell types were required: renal tubule-forming cells, such as kidney spheroids, endothelial progenitors (ECFCs), and MSCs which are needed to generate pericytes. Taken together, these studies indicate that for successful regeneration of renal parenchyma and renal vessels in a diseased kidney, transplantation of mixed cell types will be required.

In summary, the origin of regenerating tubular cells is from fully differentiated tubular epithelia, but at the same time these cells may acquire some features of unipotent epithelial stem-like cells that can clonally expand and become replication competent under specific proliferation stimuli. However, most studies examining the origin of tubular regeneration have been performed in AKI mice models induced by I/R injury. It is possible that different regenerative mechanisms may be involved in other kidney injury models.

Adult Renal Stem/Progenitor Cells Expanded Ex Vivo

Many studies have characterized adult renal stem/progenitor cells using in vitro cultures. These cell populations might result from cell-culture-



Proximal tubule
Distal tubule
Nephrons of rainbow mouse at initial time point
Collecting duct
Henle's loop
Chase period (homeostasis/repair)
Urinary shedding
Wnt-responsive clone
Formation of lineage-restricted clones
Wnt-responsive clone

Fig. 3 Cartoon showing how renal tubular cells regenerate during steady state and after injury at the clonal level. “Rainbow” mice permanently label individual kidney cells from embryonic development and throughout adult life (top). Lineage restricted clones that are fated to proximal, distal, or collecting duct tubules renew and regenerate the mouse kidney throughout life (bottom). (Adapted from Rinkevich et al. [85])

induced changes in morphology, behavior, and marker expression, although they are still possibly clinically useful. Development of methods to expand nephron-forming cells from adult kidney while preserving stem/progenitor function could supply a source for cell therapy.

Renal stem/progenitor cells have been reported to exist in or were isolated from various locations in adult kidneys, including the renal papilla, interstitium, tubular epithelial cells, Bowman's capsule, decapsulated glomeruli, juxtaglomerular apparatus, and collecting ducts. They have been identified with various assays, such as label-retaining assays, clonogenic assays, sphere or spheroid assays, flow cytometry using cell surface markers, lineage tracing studies, and side population (SP) assays [87].

Label-retaining cells (LRCs) identified in vivo by BrdU labeling exhibit a characteristic slow cycling of tissue-specific stem cells. Maeshima et al. showed that LRCs are found in renal epithelial tubular cells of rat kidney and that they reentered mitosis and differentiated into tubular epithelia in response to renal ischemia; thus, contributing to tubular regeneration after damage [88]. Oliver et al. identified a population of LRCs in the interstitium or upper papilla of adult rodent kidneys [89]. These LRCs can rapidly proliferate in response to ischemic insult, suggesting that they may play a role after acute injury. However, the LRCs from these reports might represent transiently amplifying cells rather than stem cells. Proof of the existence of a pluripotent adult renal stem cell population with long-term self-renewal capacity and clonogenicity remains to be shown.

Kitamura et al. screened for stem cells in various regions of the postnatal rodent kidney by the dissection of various nephron segments and culture after dissociation to single cells [90]. They established clonally expanded cells from the S3 segment of rat proximal renal tubules, which are known to be most susceptible to injury and to have the highest proliferation rate in nephron segments. The established cell line showed features of stem cells and could be maintained long term without transformation.

Buzhor et al. was the first to establish 3D spheroid cultures of human kidney epithelial cells retrieved from human nephrectomy tissue samples by suspension cultures in low-attachment conditions [91]. The human kidney spheroids upregulated certain renal developmental and "stemness" markers, including *PAX2*, *SALL1*, *SIX2*, *WT1*, *NANOG*, and *GPC3*, and indicated mostly an EpCAM(+)CD24(+)CD133(+)CD44(+) phenotype. When grafted in low cell numbers onto the CAM of chick embryos, the spheroid cells exclusively reconstituted renal tubular epithelia of different nephron segments. More recently, Harari-Steinberg et al. grew 2D cultures from primary human kidney cells and then cultured them as 3D spheroids, finding that the renal epithelial identity lost in 2D culture conditions was reestablished; furthermore, upon grafting of human kidney spheroids into CKD mice, long-term engraftment and differentiation into kidney structures in mice was achieved and kidney function improved [92]. In addition, the kidney spheroids were shown to confer an antifibrotic paracrine effect, as evident in transwell experiments, by downregulating collagen production from cocultured fibroblasts. Notably, the same affect was obtained when using kidney spheroids derived from kidneys from patients with ESRD (Fig. 4).

Bombelli et al. reported a modified sphere-formation protocol to generate nephrospheres from normal human adult kidneys [93]. The cultured nephrospheres activated stem cell pathways, contained cells at different levels of maturation, and generated 3D tubular structures both in vitro and in vivo. The group identified a quiescent PKH^{high} stem cell population within the spheres that demonstrated in vitro self-renewal capacity and differentiation potential into epithelial, endothelial, and podocyte progenies.

Bussolati et al. isolated tubule cells expressing a hematopoietic stem cell marker, CD133, from human renal cortex [94]. These cells expanded, differentiated in vitro into epithelial or endothelial cells and showed developmental potential to form tubule-like structures and functional vessels. They were also incorporated into tubules when intravenously injected into immunodeficient mice with AKI induced by glycerol-induced rhabdomyolysis.

Dekel et al. identified nontubular cells that expressed the stem marker SCA1 as MSC-like progenitor cells in the papillary interstitial space of the

activation of endogenous repair
Fibrosis inhibition
Cell replacement

Fig. 4 Scheme of potential future use of kidney spheroids as an autologous cell treatment. Kidney cells extracted from a patient with CKD are first expanded in monolayer (2D) conditions, and then transferred into 3D-promoting culture conditions to obtain nephrospheres. These, in turn, can serve as the starting point for both autologous cell treatment, and for various in vivo assays. (Adapted from Harari-Steinberg et al. [92])

adult mouse kidney [95]. The cloned renal SCA1(+) LIN(−) cells showed in vitro differentiation potential for myogenic, osteogenic, adipogenic, and neural lineages; the SCA1(+)LIN(−) cells also adopted a tubular phenotype when injected directly into the renal parenchyma of mice with AKI induced by I/R.

A group led by Paola Romagnani has reported that a population of CD24(+)CD133(+) cells localized at the urinary pole of the Bowman's capsule in adult human, mouse, or rat kidneys represent renal progenitors that give rise to both glomerular podocytes and renal tubular epithelia. Clonally expanded CD24(+)CD133(+) cells also contributed to the regeneration of renal tubular structures and significantly ameliorated kidney damage after their intravenous injection into immunodeficient mice with AKI induced by rhabdomyolysis [96].

Bruno et al. found that human glomeruli deprived of Bowman's capsule contain a population of CD133(−)CD146(+) cells that express MSC markers and renal stem cell markers, CD24 and PAX2 [97]. These MSCs exhibit self-renewal capability, clonogenicity, and multipotency capable of osteogenic, adipogenic, and chondrogenic differentiation. In addition, they are able to differentiate into endothelia, epithelial cells expressing podocyte markers and mesangial marker-expressing cells.

Buzhor et al. established a 2D and low-density clonal culture of epithelial cells from adult kidney tissue of nephrectomized patients, in which the reactivation an embryonic mesenchymal marker, NCAM1, was observed in a specific cell population that attained a stem/progenitor state [98]. The isolated NCAM1(+) cells showed proximal tubular origin, expressed early nephron progenitor markers, such as PAX2, SALL1, SIX2, and WT1, and acquired a mesenchymal fate, indicated by high VIMENTIN and reduced E-CADHERIN expression levels. The cell population showed clonogenic potential as single cell cultures, generated 3D kidney spheroids, and differentiated into tubular structures when grafted onto the CAM of chick or into the subcutaneous space of immunodeficient mice. Importantly, NCAM1 is a molecular marker identified in vitro in linage-restricted adult kidney clones assigned to proximal tubule origin [86].

Gupta et al. isolated multipotent renal progenitor cells (MRPCs) from adult rat kidneys by using low-density culture conditions for 4–6 weeks that were similar to those used for the culture of bone marrow–derived multipotent adult progenitor cells [99]. These MRPCs expressed OCT4 and PAX2 and differentiated into tubular structures in vitro and in vivo. However, these cells displayed spindle-shaped morphology, suggesting nontubular and possibly extrarenal origin.

Pippin et al. performed lineage tracing experiments to show that cells of renin lineage in the juxtaglomerular compartment serve as progenitors of glomerular podocytes and parietal epithelial cells in experimental glomerular disease [100]. After a decrease in podocyte number by cytotoxic anti-podocyte antibody, a significant increase in the number of labeled cells of renin lineage was observed in glomeruli; the labeled cells were distributed along Bowman's capsule, within the glomerular tuft, or in both locations, and expressed markers for glomerular parietal cells or podocytes.

SP cells are defined as a cell population that can rapidly efflux DNA-binding dyes, such as Hoechst 33342 and Rhodamine 123, and may exhibit stem cell–like characteristics, including the expression of specific membrane transporters associated with stemness. SP cells in the bone marrow overlap with hematopoietic stem cells, and have also been isolated from other tissues, including the adult kidney [101]. Challen et al., used stringent isolation procedures and found that renal SP cells represent 0.1% of the kidney. These cells showed multilineage differentiation potential into osteocytes and adipocytes in vitro, and into several nephron segments in vivo at low efficiency after their injection into an adriamycin-induced acute glomerular injury model. However, despite stringent selection, the cell population remained heterogeneous, including a monocytic fraction, which may result in the apparent phenotypic plasticity. The injection of adult kidney SP cells did not show significant tubular integration in acute renal damage models. The SP population derived from other organs than bone marrow, including kidneys, does not always show characteristics of tissue-specific stem cells.

Lee et al. isolated mouse kidney progenitor cells (MKPCs) with MSC properties that reside in the mouse kidney interstitium of the medulla and papilla [102]. MKPCs displayed features including spindle-shaped morphology, self-renewal of more than 100 passages without evidence of senescence, and plasticity; they also demonstrated multipotent differentiation potential into endothelial cells and osteoblasts in vitro and endothelial and tubular epithelial cells in vivo. Intrarenal injection of MKPCs in immunodeficient mice with I/R injury rescued renal damage both histologically and functionally and reduced mortality; some of the MKPCs formed vessels with RBCs inside and incorporated into renal tubules.

Li et al. identified an MSC-like population in the adult mouse collecting duct that undergoes an epithelial-to-mesenchymal transition to form clonogenic, long-term self-renewal and retains a capacity to form epithelial structures in vitro and in vivo [103]. After extensive passages, these kidney MSC-like cells selectively integrated into the AQP2(+) medullary collecting duct when microinjected into the kidneys of neonatal mice. Further studies revealed that a *Wnt4*-expressing interstitial population intercalates into the collecting duct in neonatal kidney, giving rise to the MSC-like cells.

Finally, the Clevers group utilized the adult human kidney to expand 3D epithelial structures that recapitulate aspects of the kidney of origin. They found that WNT pathway stimulation leads to long-term growth of primary tubular epithelial organoids termed tubuloids. Human tubuloids which originate from an adult kidney cell mix which operatively can be viewed as stem/progenitor cells represent proximal as well as distal nephron segments and can be used to model infectious and hereditary kidney disease in a personalized medicine platform [104].

In summary, various types of adult renal stem/progenitor cells have been identified by different methods. Although these adult stem/progenitor cells have been reported to contribute to the epithelia of glomeruli and renal tubules like embryonic progenitors, they may represent a different cell population from embryonic NPCs and possess different gene expression profiles and cellular origins. Detailed characterization of these cells and examination of the therapeutic potential of each stem/progenitor cell population are still pending.

Stem Cell Niche in Adult Kidney

Stem cells are usually located in specific anatomic locations termed “niches,” which regulate how stem cells participate in tissue generation, maintenance, and repair [105]. Stem cells are typically located in deep, narrow tissue niches, while transiently amplifying precursor cells and differentiated cells at various stages of maturation lie in the progressively more distal cell layers. In addition to heterologous cellular components, any given niche is thought to consist of an extracellular matrix and other noncellular constituents. Both paracrine and metabolic factors could also serve as a niche, since they respond to exogenous signals via a sensing system consisting of the nervous and/or circulatory system. Accordingly, the perivascular site is considered a stem cell niche [76].

Other studies have indicated that the MSC compartment, which resides in the connective tissue of most organs (including kidneys), is capable of differentiating into osteoblasts, adipocytes, and chondrocytes, as a result of its perivascular location. Based on similar marker genes, such as CD146, and differentiation potential into osteoblasts, adipocytes, and chondrocytes, it has been hypothesized that vascular pericytes may represent the MSC population within any given organ. Indeed, pericytes are quiescent, slow-cycling cells at baseline; however, in the angiogenic stage they show high proliferative potential, capacity for self-renewal, and the ability to generate osteoblasts, chondroblasts, fibroblasts, and pre-adipocytes in vitro, consistent with adult stem cell characters [76].

The microvasculature of the renal papilla is particularly rich in pericytes that regulate microvascular integrity in the peritubular capillary network and give the descending vasa recta, the arteriolar segments supplying blood to the medulla, their contractile function. Therefore, the MSC compartment residing in the renal papilla might be linked to the perivascular niche. Consistent with this hypothesis, Lee et al. [102] identified MKPCs with MSC properties that reside in the mouse kidney interstitium of the medulla and papilla in close association with endothelial cells. Similarly, a report by Oliver et al. [89] showed LRCs with several characteristics of adult stem cells in the papillary interstitium and collecting duct. Finally, Dekel et al. [95] demonstrated that nontubular SCA1(+) multipotent progenitor cells are found mainly in the papillary interstitial space of adult mouse kidney.

In summary, the renal papilla has been a candidate stem cell niche in kidney. However, there are relatively little data on kidney stem cell niches compared with other organs. Thus there is still much to learn about the identify of these niches and their mechanisms for regulating renal stem cells.

CSCs in Kidney

CSCs drive tumor growth by their self-renewal, as well as by giving rise to a large population of differentiated progeny that make up the majority of cells in a tumor [7–9]. Their ability to initiate tumor growth when grafted into immunocompromised mice demonstrates that CSCs exist in a variety of human tumors. Specific signaling pathways play a functional role in self-renewal and/or differentiation of CSCs, suggesting targeted therapies are possible. In addition, identification of markers that enable isolation of CSCs, which are a minority population of tumor-constituting cells, from whole tumor tissues should help clarify the biological properties of CSCs. To date, relatively a small number of studies have reported the identification of renal CSCs [106].

CSCs in Adult Renal Cell Carcinoma (RCC)

RCC is a common form of urologic tumors, accounting for approximately 2% of total human malignancies and >90% of cancers in the kidney with an annual increasing incidence [107]. Major subtypes include clear cell RCC, which is the most common form, papillary RCC, and chromophobe RCC; the remaining subtypes are very rare. Although marked advances in treatment of RCC have been made over the past decade due to earlier detection and increased treatment options, including targeted agents against VEGF and mTOR pathways and immunotherapies, advances in diagnosis, local management, and systemic therapy based on the molecular biology of RCC are needed to achieve better long-term survival. RCC is considered to originate from a mutated tubular population with stem/progenitor cell properties, much like in other organs [106]. Renal CSCs have been isolated from RCC using different stem cell markers or by functional approaches similar to other stem cell isolation methods, including sphere formation or SP assays.

Bussolati et al. identified a population of tumor-initiating cells from RCC and renal undifferentiated carcinomas by means of cell sorting with a mesenchymal marker, CD105 [108]. These cells were cloned in stringent culture conditions and displayed tumor-initiating ability, generating serially transplantable carcinomas. Functionally, CD105(+) cells are clonogenic and able to generate spheres. Moreover, these cells differentiate into epithelial cells in vitro and in vivo to recapitulate the histological pattern of the tumor. Interestingly, CD105(+) cells do not express CD133, which is a candidate marker for adult renal progenitors and also expressed in CSCs of tumors in other organs, such as the nervous system, colon, prostate, pancreas, and lungs [106]. While CD105 has been proposed as the main marker for CSCs in RCC, many studies report that CD105(−) cells also show CSC-like features [106].

Zhong et al. selected cells from a renal cancer cell line, SK-RC-42, that have the ability to form spheres in serum-free medium supplemented with EGF and bFGF [109]. The cell population expressed several “stemness genes,” including OCT4, BMI, β-catenin, and Nanog, showed resistance to chemotherapeutic agents and irradiation, and have higher in vivo tumorigenicity than monolayer adherent cells. Addla et al. used the SP assay to identify renal CSCs [110]. SP cells isolated from renal carcinomas expressed mesenchymal markers including CD105, but not CD133, and showed high proliferative potential and an ability to give rise to differentiated spheroids. Other candidate stem cell markers, such as CD133, CXCR4, and CD44, and enzymatic activity of aldehyde dehydrogenase 1 (ALDH1) have also been used to isolate and characterize CSCs in RCC [106]. However, the detailed characteristics and roles of these cell populations in carcinogenesis or their clinical significance are unknown.

CSCs in WT

WT, also called nephroblastoma, is the most common type of kidney cancer in children and fourth most common among all childhood cancers [111]. WT is typically composed of three elements: undifferentiated blastema, stroma, and tubular structures at varying levels of differentiation, which together resemble the nephrogenic zone of a normal developing kidney. Thus, it is widely accepted that WT arises from transformed renal stem cells, which maintain the undifferentiated blastemal component of the tumor and which maldifferentiate to give rise to tubular elements. Thus, while embryonic nephrogenesis is driven by normal renal stem cells, WT is propagated by an equivalent transformed population, termed WT

CSCs [112]. Reports suggested that nephrogenic differentiation in the tumor was deranged, as the transcription factors that normally specify renal stem/progenitor cells (SIX2, WT1 and PAX2) were epigenetically dysregulated in the WT blastema with aberrant DNA methylation at the promoter regions [113] and abnormal chromatin modifications [114]. These changes may lead to an enhanced activation and accumulation of early stem/progenitor cells that fail to undergo the normal kidney-specific differentiation program.

Pode-Shakked et al. reported that NCAM1, a marker for normal embryonic renal progenitors, is also a putative CSC marker in WT based on microarray data [115]. It was further found that NCAM1(+) cells showed the expression of a “WT-stem” signature gene set and clonogenicity. The group also performed serial transplantation of a NCAM1(+) cell fraction within WT into immunodeficient mice, demonstrating that NCAM1(+) cells give rise to new tumors as well as NCAM1(−) differentiated cells. Therefore, the NCAM1(+) population fits the criteria of CSCs, as they can self-renew and possess multipotency in vivo. Moreover, they demonstrated that targeting the human NCAM(+) cell fraction with an anti-NCAM antibody-drug conjugate resulted in loss of the WT CSCs, both in vitro and in vivo [115].

Shukrun et al. purified the CSC population in WT and revealed that NCAM1(+)ALDH1(+) cells had tumorigenic properties and exclusively localized within the blastemal compartment of the tumor, but that NCAM1(+)ALDH(−) or NCAM1(−)ALDH1(+) cells did not [116]. Surprisingly, they showed that ALDH1(+) WT CSCs are not the most primitive cell population in WT blastema, but correspond to more committed epithelial progenitors that have reduced expression of several renal progenitor markers including SIX2, OSR1, PAX2, CITED1, WT1, and SALL1 and relatively high expression of epithelial markers. Thus, it can be deduced that WT CSCs, which sustain tumor growth, can both dedifferentiate toward $\text{SIX2}^{\text{high}}$ blastemal cells and differentiate into mature epithelial structures.

More recently, Raved et al. used primary WT specimens from 24 patients and their medical records to demonstrate that the NCAM1(+) ALDH(+) CSC population significantly correlates with adverse clinicopathologic parameters and poorer prognosis; this underscores the role of the CSCs in disease progression and supports assessing for these markers for better risk stratification of WT [117].

Towards Clinical Applications and Practical Use

One of the remaining challenges in the directed differentiation of PSCs is the induction of mature collecting duct cells that include principal and intercalated cells. Additionally, PSC-derived embryonic kidney stromal progenitors have not been generated. Another challenge is that PSC-derived kidney organoids remain very immature. Possible solutions for the latter include vascularization and the addition of physical stimuli, such as blood or urinary flow and shear stress. To that end, organ-on-a-chip technology has already been used to mature human iPSC-derived nephron structures by incorporating a vascular network of endothelial cells [118].

To generate functional kidneys, human PSC-derived kidney tissues need to be connected to larger vessels, and the collecting ducts need to be attached to a renal pelvis and ureters. To generate larger kidneys, one promising approach is to utilize the embryonic niche of experimental animals including genetically manipulated pigs. Additionally, several studies have aimed to generate kidney organs by repopulating embryonic kidney and vascular progenitors inside scaffolds composed of the extracellular matrices that remain after kidney decellularization [119]. Another approach is to artificially generate 3D kidney tissues with a 3D printer [120].

To harness the beneficial paracrine effects of human iPSC-derived kidney progenitors against AKI, identifying the molecular nature and elucidating the protective mechanisms would facilitate more effective cell-based therapies. Also, human iPSC-based cell therapies that prevent the progression of CKD will hopefully be developed. Other research applications that could utilize PSC-derived kidney lineage cells include disease modeling, drug discovery, and toxicology screening. The discovery of novel drug compounds using PSC-based disease models is anticipated for intractable kidney disorders, such as autosomal dominant polycystic kidney disease (ADPKD) [5, 6].

As for fetal-derived cells, several therapeutic approaches can be envisioned. Fetal kidney-derived NCAM1(+) progenitors have already shown clinical benefit in a mouse model of CKD, demonstrating an ability to halt disease progression [43]. Considering the low immunogenicity of fetal kidney cells, it may be possible in the future to generate a tissue bank of cell for regenerative purposes. Furthermore, an equivalent population of fetal-like progenitors could be isolated from iPSC-derived kidney organoids, to generate autologous cells for treatment of kidney disease.

Similarly, although the adult kidney does not harbor bona fide multipotent stem cells, tubule-forming cells established from adult kidneys have already shown to successfully improve renal function in mouse models [92]; this paves the way towards potential patient-specific cell therapies or for the utilization of the bioproducts from these cells in a cell-free regimen. The identification of a synergistic effect of tubule- and vessel-forming cells for differentiation capacity in vivo also has the potential for beneficial effects on diseased kidneys, although the clinical benefits of this combination still need to be determined.

Regarding renal CSCs, a definitive selective marker for the isolation and targeting of these stem cells is still lacking. Future studies to identify appropriate selection markers and to understand the intracellular pathways that regulate renal CSC maintenance and differentiation should lead to new therapeutic strategies.

Conclusions

During the last decade, kidney regeneration research using human PSCs has substantially advanced. Directed differentiation protocols that induce human PSCs to differentiate into embryonic kidney progenitors, NPCs and UB cells, have been developed, and kidney organoids containing nephrons and collecting ducts can be generated from these progenitors. Development of novel therapeutic strategies using PSC-based technologies, such as cell therapies and the transplantation of reconstructed kidneys, is expected during the next decade.

Concomitantly, the ability to isolate and culture tubule-forming cells from both fetal and adult human kidneys is a promising milestone that could be harnessed in the future to develop cell-based, potentially autologous treatments. While treatments using adult cells would likely require a combination of cell types, the ongoing improvements in our understanding of kidney lineages and cell biology suggests that this is a possible, albeit yet still a challenging goal.

Both RCC and WT possess CSCs with high tumorigenic ability and resistance to chemotherapy and radiotherapy, thus providing a rationale for new therapies targeting these stem cell populations. The tumor formation model with WT CSCs could help us better understand kidney development and generate anticancer therapeutic strategies.

Abstract

Kidney function undergoes developmental changes, including postnatal adaptation of nephron recruitment until approximately 18 months of age and glomerular hypertrophy thereafter. Accurate assessment of kidney function across post-conceptual age is important and needs to incorporate factors associated with the person (e.g., body habitus, growth, muscle mass, health status, illnesses, inflammation, and intra-personal variability), measurement technique (e.g., endogenous biomarkers, exogenous techniques, or imaging studies), and interpretation of measurements (e.g., equation used, correction factors, indexing to body surface area, or extracellular volume).

While nephron endowment would be the most important factor for an accurate clearance calculation of more than 60% of drugs processed by the kidney, this cannot be assessed directly. Effective renal plasma flow (ERPF) may be better to assess nephron endowment as it does not undergo autoregulation or hyperfiltration, in contrast to glomerular filtration. However, glomerular filtration rate (GFR) is still the best surrogate tool for kidney function assessment.

The gold standard to measure kidney function is inulin clearance; however, this is impractical. Measurement of GFR using either radiolabeled or cold exogeneous substances such as iohexol, iothalamate, etc. now serve as replacement for more accurate GFR determinations. In the clinical routine, endogenous markers are used, especially serum creatinine and cystatin C. Health care providers need to know when to use which endogenous biomarker(s).

In this chapter we will discuss historical aspects of kidney function measurement, exogenous and endogenous methods, and the technical aspects of assessment or interpretation in health and sickness, from the neonate to the transition-age periods.

Keywords

Clearance · Inulin · Para-Aminohippuric Acid · Effective renal plasma flow · Filtration Fraction · Nephron endowment · Creatinine · Cystatin C · Beta-trace Protein · IDMS traceability · Certified Reference Intervals · Reference Intervals · Race · Transition to adulthood

Abbreviations

AYA	Adolescents and young adults
CAKUT	Congenital anomalies of the kidneys and urinary tract
CKD	Chronic kidney disease
CysC	Cystatin C
DMSA	Dimercapto succinic acid
DTPA	Diethylenetriamine penta-acetic acid
EDTA	Ethylenediamine tetra-acetic acid
eGFR	Estimated glomerular filtration rate
ERPF	Effective renal plasma flow
GFR	Glomerular filtration rate
MAG3	Mercaptuacetyltriglycine
PAH	Paraaminohippuric acid

Summary and Key Points

- Kidney function cannot be assessed directly. Glomerular filtration rate (GFR) is currently the best surrogate of renal function.
- The gold standard for GFR measurement is inulin clearance, but it is impractical. However, there is good agreement with nuclear medicine

methods such as ^{99}Tc iohexol ^{99}Tc DTPA, ^{51}Cr EDTA, and, iothalamate. Iohexol and iothalamate can also be performed without radiolabeling.

- Creatinine, albeit a marker afflicted with many technical problems, remains the most commonly used endogenous biomarker of kidney function measurement.
- Cystatin C (CysC) is a superior biomarker of kidney function that can be used even at 1 day of life, but its availability is limited.
- Beta trace protein and beta-2 microglobulin may be future endogenous biomarkers used to assess kidney function.
- Exogenous methods to directly measure GFR are impractical in the daily clinical routine. Estimated GFR is more suitable and it should be based on serum creatinine and when available, CysC.
- Special populations require customized approaches for measurement and interpretation of kidney function.
- In the transition age, adolescents' eGFR calculation changes as soon as they turn 18 years of age, if reported by automatic calculation in the electronic health record.

Background

> In the kidneys are seated reasonings, and there dwells in them the faculty of discernment; they distinguish truth from falsehood, and judge what is base and what is noble. Saint Ephraem (ca 306–373 CE)

Kidney function cannot be measured directly [1]. One would have to calculate clearance which is the process of removing a marker (i.e., creatinine) over a given period of time, in this case through removal by the kidneys. It is important to measure kidney function as 60% of drugs are eliminated by the kidneys [2]. The process of glomerular filtration of plasma fluid has been known for over 170 years. In 1844, Ludwig proposed first the physico-mechanical formation of a protein-free ultrafiltrate by the renal glomeruli [3, 4]. The first biomarker of renal function was urea, which was initially isolated from urine in 1773 by the French chemist Hilaire-Marin Roeuelle. Urea preparation by the German chemist Friedrich Wöhler from ammonium cyanate in 1828 was the first generally accepted laboratory synthesis of a naturally occurring organic compound from inorganic materials [5]. Moller introduced urea clearance as a measure of kidney function in 1928–1930. He defined clearance as "the volume of blood that a 1 min's excretion of urine suffices to completely clear of urea" [6–9]. In the 1930s, during studies of the kidney tubules, investigators searched for a biomarker that would not be reabsorbed or secreted after introduction into the tubules. The ideal GFR marker must have stable concentration in the plasma, must be physiologically inert, cleared only by the kidney, and freely filtered at the glomerulus [10], without reabsorption or secretion by the tubules. Richards introduced inulin in 1934, because of its high molecular weight and its resistance to enzymes [11]. Its clearance was described by Shannon in 1935 [12]. Subsequently, inulin, which is only eliminated by glomerular filtration (without undergoing any tubular absorption or secretion), became the standard for measuring kidney function. Smith introduced the inulin clearance for renal function measurement in 1956 [4].

Kidney clearance describes the volume of plasma that is completely cleared of a substance by the kidneys per unit of time. The kidney clearance of a substance x (C_x) is calculated as:

$$C_x = U_x * V/P_x$$

where V is the urine flow rate (mL/min), U_x is the urine concentration of the substance x, and P_x is the plasma concentration of substance x. Typically, C_x is expressed in mL/min, and normalized to 1.73 m^2 body surface area (BSA) [1]. If a substance is freely permeable across the glomerular capillary and is not synthesized, transported, or metabolized by the kidney, C_x is equal to the GFR [13].

Today, we use measured GFR as the gold standard for assessing renal function [1]. As we will learn, inulin clearance has been replaced by more available exogenous substances such as ^{51}Cr-ethylenediamine tetra-acetic acid (EDTA), ^{99}Tc-diethylenetriamine penta-acetic acid (DTPA), ^{125}I-iothalamate, and iohexol. Most of these substances are labeled with a radioisotope; however, iohexol can be used hot or cold. While now serving as the new standard, these methods are impractical for daily clinical use, and endogenous markers are widely used, especially serum creatinine, albeit its many limitations.

Two important aspects have to be mentioned. Firstly, glomerular filtration only accounts for a fraction of the removal of toxins from the body, as most toxic substances are highly bound to plasma protein and require tubular secretion rather than glomerular filtration. Homer W. Smith clearly demonstrated that para-aminohippuric (PAH) acid was the most suitable agent for the evaluation of kidney plasma flow in both humans and dogs and introduced the PAH clearance which is still used in some centers today [14]. PAH clearance more closely reflects nephron endowment when compared to GFR [1]. Due to the autoregulation of the kidney, GFR can be maintained across a wider range of nephron endowment. Only when the filtration fraction is normal (the ratio of GFR/PAH clearance, which is normally about 16%) and there is no hyperfiltration, GFR will accurately reflect PAH clearance [15]. GFR may be inappropriately high due to glomerular hyperfiltration [15]. It is thought that glomerular hyperfiltration can be caused by afferent arteriolar vasodilation, as seen in patients with diabetes or after a high-protein meal, and/or by efferent arteriolar vasoconstriction owing to activation of the renin-angiotensin-aldosterone system, thus leading to glomerular hypertension [16]. Unfortunately, we do not have an endogenous biomarker of PAH clearance, even though it has a strong predictive value for long-term prognosis in hemolytic uremic syndrome [17].

Secondly, we take it for granted that kidney function should be indexed to body surface area (BSA). However, does this make sense when (a) gaining body weight increases BSA which would automatically increase your GFR and (b) the body fat is not participating in the renal clearance? Moreover, the biological principle of having a finite number of nephrons until 36 weeks of gestation and subsequently experiencing slow attrition of nephrons [18] does not match the life course of GFR. Bird questioned indexing GFR to BSA for some time and proposed to use the extracellular volume (ECV) instead [19, 20]. After birth, nephrons are slowly recruited until about 18 months [21] and from then on, the normalized GFR should gradually diminish due to nephron attrition, but only when indexing GFR to ECV does this happen [19, 20, 22]. Peters et al. published a robust formula for the calculation of ECV [23], but there is no consensus about indexing GFR to ECV rather than BSA.

The Importance of Measuring Kidney Function

Measuring kidney function guides clinical practice, drug dosing, and research. Identifying impaired kidney function is paramount as more than 60% of drugs are cleared by the kidney [2]. The preservation of kidney function is a widely important goal for managing acute and chronic kidney disease conditions. The progression of chronic kidney disease (CKD) is monitored by serial GFR assessment [24]. Assessment of kidney function is also important as a predictor of outcomes, for instance, in heart failure [25, 26]. Health providers must therefore be very familiar with the various methods of assessing kidney function, be aware of the strengths and limitations of the various techniques, and be especially mindful about technical aspects when using either endogenous or exogenous markers of kidney function [1, 27].

Current Gold Standard/Exogenous Methods

There are significant limitations to the inulin clearance, including limited availability and methodological aspects for the quantitation of inulin in the blood and urine samples with substantial inter- and intra-patient variability [1]. However, if inulin clearance is employed, we would recommend a bolus injection of 5000 mg of inulin per 1.73 m^2, with a maximum dose of 5000 mg. Inulin has to be infused at a constant rate, over 30 s. Extravasation must be avoided, as this would result in an overestimation of GFR. Sampling times must be 4 or more, with an ideal extension to 240 min. For the evaluation, a two-compartmental model using the concentrations at the actual time points must be utilized, ideally with NonMem or other appropriate pharmacokinetic software programs like WinNonLin [28]. It is unclear if any centers are still utilizing inulin clearance. There is only one supplier left in the world who provides Inutest®, and at a prohibitive cost.

In the 1970s and 1980s, inulin clearance studies were gradually replaced by nuclear medicine methods. These methods typically involve the injection of a radiolabeled pharmaceutical with features similar to inulin, although none of them have zero plasma protein binding, which would be essential for pure glomerular filtration measurement. Iohexol is not radiolabeled and has only 2% plasma protein binding, making this the preferred method [29]. The quantitation of the pharmaceutical through the simple nuclear medicine method of simply counting the disappearance of the isotope counts over time allowed for faster and more accurate measurement of GFR. The most commonly used exogenous markers of GFR are listed in Table 1. Each center will have experience with one particular method and will have particular reasons for choosing one method over the other. For instance, at the University Medical Centre Groningen, Netherlands, ^{125}I-iothalamate is used combined with ^{131}I-Hippuran for the simultaneous determination of ERPF [30]. ^{131}Iodine emits radiation in the form of medium energy gamma rays and mostly beta particles, whereas ^{125}Iodine emits soft gamma radiation with a maximum energy of 35 KeV so that both isotopes can be identified with different cameras.

Comparison of Exogenous GFR Methods, Technical Aspects

Iohexol is theoretically superior to other exogenous markers because of its low plasma protein binding: the higher the plasma protein binding, the larger the proportion of clearance contributed by tubular secretion, leading to the overestimation of GFR. In practice, however, the accuracy of iohexol GFR estimates demonstrate considerable scatter [42]. Clinical studies comparing inulin clearance with nuclear medicine scans favor ^{51}Cr EDTA, which showed the least bias and best agreement in both transplant and non-transplant patients [1, 32]. In a study of 40 renal transplant patients, the error was only between +2.2 to

Table 1 Commonly used exogenous markers of glomerular filtration rate (GFR)

GFR Compound	Places of use	Major features	Plasma protein binding
^{51}Cr-ethylenediamine tetra-acetic acid (EDTA) clearance [31]	Europe	Tight binding of chromium to pharmaceutical, radiation dose 0.074 MBq/kg to 3.7 MBq/kg. Can be combined with DMSA or MAG3 imaging study [32]. Not available in the USA and Canada. Beta-particles from ^{51}Cr can be carcinogenic.	12.2% [33]
^{99}Tc-diethylenetriamine penta-acetic acid (DTPA) [34]	Most of the world except Europe	Often used together with imaging, maximal dose 37 MBq, (i.e., higher than ^{51}Cr EDTA). If DTPA gamma camera images and relative function are required, the dose should be higher [32].	11.0% [33]
^{125}I-iothalamate [35–37]	USA	May allow for the simultaneous assessment of extracellular fluid volume and GFR [30]. Can be combined with ^{131}I-Hippuran for simultaneous determination of ERPF [30]. Up to 38% overestimation when compared to inulin in healthy subjects [38]. Used as subcutaneous injection in Montreal [39].	9.6% [33]
Cold iohexol [40, 41]	Scandinavia, North America	No radiation exposure, also has lowest plasma protein binding.	2.0% [29]

+2.8 mL/min/1.73 m^2 when comparing ^{51}Cr EDTA and inulin clearance [43]. ^{51}Cr EDTA is not available in the USA and Canada.

There are important technical aspects to be considered when employing exogenous methods. Perhaps the most important one is the extravasation of the pharmaceutical. Nuclear medicine methods allow for an assessment of extravasation by taking a gamma (or beta) camera picture of the injection site [1]. Samples must not be drawn before the infused substance reaches equilibrium with the entire extracellular volume [1]. Errors can also occur if the analysis method does not include a proper nonlinear two-compartmental model [1]. Many centers only employ two time-point measurements instead of three, which makes it impossible to reveal more than usual equilibration of the pharmaceutical between both compartments [1]. In Fig. 1, we show a typical 2-compartmental model of the isotope distribution. As seen from this figure, sampling should not start before 45 min. In patients with dyslipidemia, the time to equilibration can be much longer [44]. In patients with very low GFR, late samples have to be drawn [45]. In an unpublished survey among Canadian pediatric nephrology centers, the majority of centers employed only two sampling points and not three, which may result in significant overestimation of GFR.

Furthermore, most centers employ a single shot plasma clearance method, even though inulin clearance uses timed urine collections. The major disadvantage of plasma clearance is the duration of testing needed to calculate the clearance curve accurately, which can take up to 8 h [45]. As an alternative, urinary clearance techniques are another direct method that can be used to measure GFR, but these remain inconvenient and associated with errors around the timing of urine collections. We evaluated this in our center and found a significant difference when comparing plasma disappearance with a urinary method [46]. The mean (with standard deviation) plasma isotope GFR of 60.7 ± 24.9 ml/min/1.73 m^2 compared to urinary isotope GFR of 52.0 (28.0) ml/min/1.73 m^2 was statistically significant (p-value <0.001). The urinary clearance of ^{99m}Tc-DTPA was calculated using the urinary clearance equation:

$$GFR_{i_{Urine}} = \frac{U_i \times V_i}{(T_i - T_{i-1}) \times \exp\left[0.5 \times (\ln P_i + \ln P_{i-1})\right]}$$
$$\text{where } i = 1, 2, 3 \text{ (sample)}$$

$$\begin{aligned} GFR_{Urine} &= median(GFR_1, GFR_2, GFR_3) \\ &\quad \times \left(\frac{1.73}{BSA}\right) \quad \text{where } BSA \\ &= 0.007184 \\ &\quad \times \left(height^{0.725} \times weight^{0.425}\right) \end{aligned}$$

where U_i is the urinary concentration of ^{99m}Tc-DTPA adjusted for isotopic decay rate, V_i

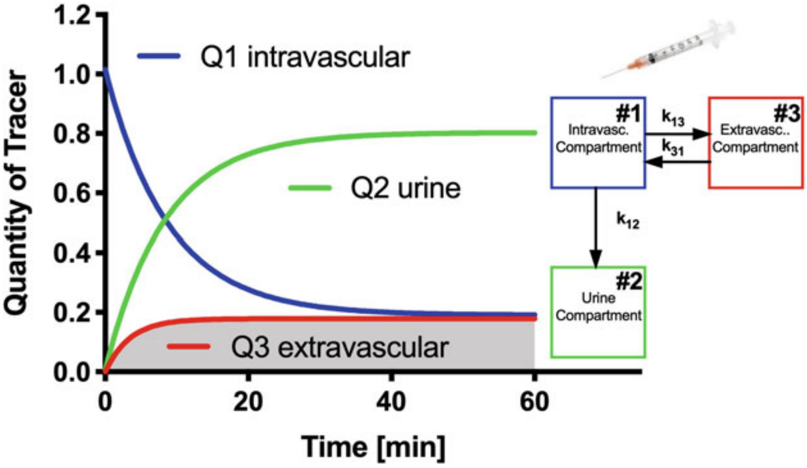

Fig. 1 Nonlinear 2-compartmental model of pharmaceutical disappearance after a single shot intravenous application of a GFR marker. Abbreviation: *Q* quantity

is the urinary volume, and P_i is the plasma concentration of ^{99m}Tc-DTPA adjusted for the isotopic decay rate, and T_i and T_{i-1} are the two time points during which the urine volume was collected [46]. Although plasma and urinary iGFRs were highly related ($R^2 = 0.86$), plasma isotope GFR increasingly overestimated urinary isotope GFRs at lower GFR levels [46]. However, urinary isotope GFR measurements are not very practical. Another problem is the timing of the sampling and the common practice of simply calculating the slope of the log-transformed isotope counts, rather than plugging in the exact counts with exact time points, in a two-compartmental pharmaceutical clearance program, such as WinNonLin or WinMem [1].

One study found that very few centers employed a measurement of GFR by utilizing a single subcutaneous injection of ^{125}I-iothalamate [47], where the correlation coefficient was quite reasonable ($r = 0.97$). However, no Bland & Altman analysis was performed to assess agreement and there were many outliers. The big advantage of this approach is the avoidance of extravasation, which may explain the relatively low intra-patient variation of repeated subcutaneous ^{125}I-iothalamate clearance (average maximum coefficient of variation was 7%) [47]. Given that proper nonlinear multi-compartmental models need to be utilized for accurate measurement of the isotope disappearance, it is understandable that not many centers utilized this approach.

Ideally, each pediatric nephrology provider should meet with their nuclear medicine department and review the often decade-old protocols to ensure that:

1. Images of the injection site are available to account for extravasation.
2. Sampling does not start too early (minimum 60 min and in nephrotic patients, possibly 90 min).
3. Three sampling points are utilized.
4. Two-compartmental nonlinear models with exact time points after injection are employed, rather than a simple calculation of the slope of the regression line of the log-transformed isotope counts.
5. The simple old Brøchner-Mortensen correction for the slope-intercept technique that is frequently used in old protocols is replaced [48].

The notable accuracy and reproducibility of GFR measurements will improve after the implementation of all of the points noted above. Providers should not be surprised if GFR results are 8–10% lower than previously noted after implementing the steps above, especially at lower levels of GFR.

Unfortunately, there is a paucity of meta-analyses of studies comparing inulin clearance with plasma and urine nuclear medicine GFR methods. We are only aware of one systematic review which concludes that there is at least moderately strong evidence suggesting that renal clearance of ^{51}Cr-EDTA or iothalamate and plasma clearance of ^{51}Cr-EDTA or iohexol are sufficiently accurate methods to measure GFR [49].

Fluorescent GFR Markers

Recently, two novel fluorescent markers that can provide accurate real time assessment of GFR have been studied in humans [50–52]. Each of both markers has been shown to be freely filtered by the glomerulus without tubular secretion or absorption. In addition, each of these markers do not undergo extrarenal metabolism, are not protein bound, or affected by medications. The study by Rizk et al. used a large 150-kD rhodamine derivative and small 5-kD fluorescein carboxymethylated dextrans which shows a linear correlation with measured iohexol GFR in 32 adults [50]. Like Inulin, 5-kD fluorescein carboxymethylated dextrans are carbohydrate polymers that are commercially available. Furthermore, the dextrans are neutral in charge like inulin; however, the carboxyl groups will likely cause an overall negative charge of the molecule [53]. It is important to note that the method proposed by Rizk allows for sufficient time for the equilibration of the exogenous substance between the compartments, which may explain the bias towards overestimation in the lower GFR range when using this method [54]. The other fluorescent detection system translates decline in transdermal fluorescence signal of the agent into GFR measurement. These methods are still considered experimental but hold promise for real time GFR assessment at the bedside in the near future.

Impractical Aspects of Exogenous GFR Measurement

Many centers routinely perform annual GFR measurements in their patients with CKD. As stated above, inulin clearance became impractical in the 1980s, and nuclear medicine methods or cold iohexol clearance replaced inulin clearance. Non-inulin methods to measure GFR have inherent challenges. From the institution's perspective, these are the challenges: The need for a technician or a nurse trained in the handling of radioisotopes is required for nuclear medicine scans. The need for the necessary equipment to measure the radioisotope and processes for safe disposal of these isotopes is essential. Both accurate bookkeeping and a special license to hold and use radioactive isotopes are required. Based on the frequency of the test being administered, the timely delivery of the radioisotope is important, as well as the appropriate usage of the radioisotope before its decay. To ensure that the patient is safe to receive the isotope, there is a need for a pregnancy test, and documentation of past allergic reactions. From the patient's stance, these are the following drawbacks: the need to be in the hospital for an extended period, large-bore IV access for frequent blood draws, administration of IV radioisotope, in some instances, the need for iodine prior to the procedure.

Endogenous Markers of Kidney Function

Serum Creatinine

Creatinine, 2-imido-5-keto-3-methyl-tetrahydroimidazole is the internal anhydride of creatine. Creatinine is derived from spontaneous nonenzymatic, nonreversible degradation of creatine and phosphocreatine in the muscle, and approximately 2% of muscle creatine is converted to creatinine daily. Many organs, including the kidney, liver, pancreas, and testes, contribute to creatine synthesis. Creatine is taken up by the muscle against its concentration gradient. In the muscle, the ratio of creatine:phosphocreatine is approximately 1:2. Creatinine in humans under physiological conditions is considered an inert substance with some exceptions. Creatinine is low molecular weight (113 Daltons), not protein-bound, freely filtered at the glomerulus, and secreted by the tubule [55].

Creatinine was first isolated by Chevreuk, a French chemist in 1832 from "beef-tea" and named it after the Greek word flesh [56]. Liebig in 1847 confirmed the presence of creatine in the muscle of animals and described the conversion of creatine to creatinine [57]. Colorimetric assay evaluating the color development between creatinine and alkaline picrate was first described by Jaffe in 1886 [58]. Folin in 1904 first described the colorimetric method of measuring creatinine by using the Duboscq colorimeter [59] and proposed to use urinary creatinine as a measure of completion of urine collection. This method was further modified to measure creatinine in urine and blood [60]. Popper, Mandel, and Meyer revised the Jaffe principle of measuring serum creatinine and obtained levels of 0.5–1 mg/dL while serum creatinine was 1–2 mg/dL using Folin's method [61]. One of the differences was the use of a colorimeter by Folin vs. the use of a photometer by Popper. Jaffe's reaction recipe has been modified by many investigators over the years and it became apparent that non-creatinine substances in the serum would react in the presence of picric acid, and these were subsequently labelled as non-creatinine chromogens. To decrease the interference of non-creatinine chromogens, Miller and Dubos used two bacterial enzymes to decompose creatinine in blood and used the Jaffe reaction to measure total creatinine equivalent before and after the addition of these enzymes [62, 63]. Despite the advent of specific enzymatic creatinine assays, Jaffe-based creatinine assays remain widely used across the world due to its low cost and simplicity.

Jolliffe and Smith in 1931 described creatinine clearance for the first time although urea clearance was described a few years prior [64]. Although some authors in the 1920s questioned the presence of any appreciable amount of endogenous creatinine and that creatinine was synthesized in the kidney, studies in the 1930s provided evidence that creatinine was indeed present in the circulation and could be measured. Rehberg in 1926 spearheaded the concept of using exogenous creatinine to measure GFR, and while exogenous creatinine clearance was higher than true GFR, he pioneered the concept of giving an exogenous substance to study renal dynamics [65]. Further studies in humans by Shannon and Miller and Winkler demonstrated that exogenous creatinine clearance was higher than GFR measurement using inulin [12, 66, 67]. However, Miller and Winkler also noted that endogenous creatinine clearance in healthy individuals equaled to inulin clearance, and the enzymatic method for creatinine measurement was used as developed by Miller and Dubos [62, 63]. These authors also noted that endogenous creatinine clearance was higher than inulin clearance in patients with chronic glomerulonephritis. An additional study in humans with kidney disease (secondary to heart disease or intrinsic kidney disease) employed two different creatinine measurements: total creatinine chromogen and specific creatinine levels, and demonstrated that endogenous creatinine clearance is not a satisfactory marker as it overestimated GFR by inulin clearance [68, 69].

Popper and Mandel proposed the use of serum creatinine in 1937 [61], which remains to be the most widely used marker for GFR estimation in spite of the following shortcomings and technical issues:

- **Tubular secretion:** One of the reasons creatinine is not an ideal marker for estimation of GFR is its tubular secretion [1, 66, 69–72]. Specifically, in CKD, as the tubular secretion of creatinine is maintained, the proportion of secreted creatinine increases in relation to the filtered creatinine resulting in GFR overestimation. Thus, the contribution of secreted creatinine to overestimation of GFR is important and worsens even more in CKD [72]. Tubular secretion of creatinine divided by inulin clearance increases progressively from 0.16 in adult patients with normal GFR, to 0.92 in patients with GFR less than 40 ml/min [70]. In addition to secretion, creatinine may undergo reabsorption as well [73].
- **Blockade with H2 antagonists and other medications:** Blockade with H2 antagonists revealed promising results that may overcome the significant problem of tubular secretion of serum creatinine [74, 75]. The use of cimetidine protocols in children remains scarce [76]. In addition to H2 blockers, trimethoprim and fenofibrate inhibit tubular secretion of creatinine resulting in higher serum creatinine without a change in GFR.
- **Dependency on muscle mass:** The source of creatinine is creatine, which is related to the muscle mass of the individual. Males have higher muscle mass than females and children have a lower muscle mass than adults [77–79]. Thus, the normative values for creatinine change as children get older and their muscle mass increases. Cancer patients have cachexia-related muscle wasting even if they have obesity, precluding steady state measurements.
- **Dependency on nutrition:** Dietary intake of protein also plays an important role in changes in serum and urine creatinine without necessarily changes in GFR. Uncooked meat contains creatine and increasing meat intake increases creatine, and thus, increasing creatinine production and excretion. Additionally, cooking meat converts creatine to creatinine, which is then easily absorbed from the gastrointestinal tract which in turn increases serum creatinine and its excretion [80, 82].
- **Non-renal clearance:** Extra-renal clearance of creatinine should also be considered when using creatinine as a marker of GFR. An extra-renal clearance of 1.7–2 ml/min [81, 83] by the gastrointestinal tract has been described, which is negligible in a healthy adult with a creatinine clearance of ~120 ml/min, but in a

patient with CKD who has a creatinine clearance of 3–5 ml/min, this becomes relevant.

- **Issues with the analytical method:** There used to be considerable variability in the reference range for serum creatinine based on the method used for its determination [84, 85]. Proficiency testing surveys published periodically by the College of American Pathologists evaluated the variability in creatinine measurement among various methods used by different institutions across the USA, and demonstrated substantial variability [86]. Fortunately, the traceability of the creatinine measurements to higher-order reference methods (isotope dilution-mass spectrometry -IDMS- reference method) improved the accuracy of creatinine measurements in recent years [87]. Pediatric health care providers must be aware of the method used for serum creatinine measurements. Despite IDMS traceability, the original Jaffe method is influenced by chromogens such as bilirubin, ketones, some proteins, and drugs like cephalosporines [88, 89]. We are aware of the following methods for the measurement of creatinine: Jaffe, compensated Jaffe, enzymatic liquid, and dry chemistry methods. In 2015, after comparing all of these methods in 26 routine instruments representing 13 different creatinine methods and finding that CKD stage classification differed in 47% of cases, Hoste et al. wrote: “Although most creatinine assays claim to be traceable to the gold standard (ID-GC/MS), large inter-assay differences still exist. The inaccuracy in the lower concentration range is of particular concern and may lead to clinical misinterpretation when the creatinine-based eGFR of the patient is used for CKD staging. Further research to improve harmonization between methods is required.” [90].
- **Creatinine clearance with timed urine sampling:** Similar to what we wrote about urinary isotope clearance studies, creatinine clearance determinations involving timed urine collections (i.e., 24-h creatinine clearance) [69, 91] can improve the accuracy of GFR estimation. However, timed urine collections are highly inaccurate in children, difficult to perform, time consuming, and impractical [91].

Small Molecular Weight Proteins as Markers of GFR

In the search for novel endogenous GFR biomarkers that are not affected by muscle mass and diet, Jung and others proposed small molecular mass proteins as markers of GFR since they are almost freely filtered through the normal glomerular basement membrane [88, 121, 157]. In normal kidney function, these small molecular weight proteins are almost completely reabsorbed and degraded by the proximal tubular cells through pinocytosis. Several proteins have been considered good candidates for the measurement of kidney function, such as cystatin C (CysC), beta-trace protein (BTP) (analyzed in children), and beta-2 microglobulin (B2M) [93]. CysC is the best studied small molecular weight protein as a surrogate GFR marker and its superiority for the detection of mildly impaired GFR was proven in meta-analyses [94, 95]. However, all plasma or serum proteins can be influenced by circumstances in which protein synthesis is increased, as seen in hyperthyroidism [96] or decreased, as seen in prolonged low-protein diets [97]. This interaction between overall upregulated or downregulated protein synthesis is important. The clinician must be aware that such conditions can influence the serum or plasma concentration of small molecular weight proteins being used as markers of GFR. Another potential problem is hypertriglyceridemia, which can affect the concentrations of these biomarkers, as shown for CysC, where triglycerides clearly affect the CysC recovery [98]. Nonetheless, CysC, specifically, has substantially improved our ability to estimate GFR. B2M is an acute phase protein, associated with inflammation [99]. However, a recent study in unborn children with obstructive uropathy has demonstrated good results for the measurement of GFR in the fetus [100].

Cystatin C (CysC)

CysC is a low-molecular-weight protein (13.3 kDa) produced in all human cells that have a nucleus [101]. Like creatinine, CysC is filtered freely through the glomeruli, but unlike this endogenous marker, CysC is less affected by non-renal factors. The features of CysC have been described in detail elsewhere [55, 93, 102–104]. Serum levels of CysC do not correlate with any pathophysiological state other than those affecting the GFR in large patient cohorts, in keeping with a stable secretion of this low-molecular protein from most human tissues and no non-renal elimination [104]. However, very large doses of glucocorticoids have been described to increase the production of CysC [105, 106], whereas low and medium doses of glucocorticoids do not seem to alter its production [107]. Also, as discussed, thyroid dysfunction may affect CysC levels [108], although the findings are inconsistent, as in some of our recent studies, we found no association with thyroid function markers [109, 110].

The reference values for CysC obtained in a carefully selected French mostly Caucasian population are 0.75 ± 0.09 mg/L for children aged 4–19 years; 0.74 ± 0.10 mg/L for males and 0.65 ± 0.09 mg/L for females aged 20–59 years, and 0.83 ± 0.10 mg/L for individuals older than 60 years of age [111]. In the first year of life, renal function matures physiologically. Accordingly, much higher CysC values up to 2.8 mg/L were found at birth. The rapid decline after birth reflects maturation of kidney function [113–115]. After birth, CysC concentrations fall, similar to serum creatinine, whereas the estimated GFR using the Filler formula [115] slowly increases until 18 months of life [18]. New reference intervals with more detailed age distributions of CysC from central Europe have recently been published on 985 healthy people older than 25 years [116].

After these encouraging findings, additional studies suggested that the reciprocal of CysC correlates better with a gold standard GFR measurement than the reciprocal of serum creatinine [118–120]. CysC, as a marker of GFR, was found to be independent of body composition [121–123]. Current automated and rapid particle-enhanced immunoturbidimetric and immunonephelometric methods (more precise than the original radio-immuno- or enzyme-linked immunosorbent assays) [123, 124] have allowed large-scale use of serum cystatin C as a clinically useful GFR marker [124].

The diagnostic performance of CysC was compared to serum creatinine in 2002 with a meta-analysis of 46 studies, in both adults and children [125]. Pooled data analysis of 3703 individuals compared correlation coefficients between GFR and the reciprocals of serum creatinine and CysC reported significantly better correlations for CysC (mean $r = 0.816$ [95% confidence interval: 0.804–0.826]) versus creatinine (mean $r = 0.742$ [95% confidence interval: 0.726–0.758]). Receiver operating characteristic (ROC) plots were available for a pooled sample of 997 individuals, again showing a significantly better area under the [ROC] curve (mean = 0.926 [95% confidence interval: 0.892–0.960] for CysC versus mean $r = 0.837$ [95% confidence interval: 0.796–0.878]) for creatinine. This meta-analysis of cross-sectional data suggests that CysC is superior to serum creatinine for the detection of impaired GFR. Another meta-analysis of 24 studies ($n = 2007$) also confirmed that the diagnostic accuracy favored CysC [95], although, in this more recent study, the diagnostic odds ratios started to overlap, most probably due to the IDMS testing of serum creatinine.

It should be highlighted that the lack of standardization of CysC assays and internationally certified reference materials lead to similar problems as with serum creatinine, unless IDMS traceability is considered [87]. Results obtained with the two main assays that are commercially available, namely, the DAKO kit (turbidimetric, PETIA) and the Siemens Healthcare assay (nephelometric, PENIA), can be quite different, as demonstrated with reference intervals for healthy term and preterm infants. The results with the PENIA method in our study [126] were significantly lower than those reported by Harmoinen [127]. Similar problems occurred when the results of the CKiD study were re-analyzed using PENIA, which rendered substantially better results [128]. Grubb reported the first certified standardized reference material for cystatin C [129] and most commercial suppliers of CysC are now using these certified reference intervals. Unfortunately, the availability of CysC is still lacking in many parts of the world. This is despite the fact that for the best accuracy of estimation of GFR from endogenous biomarkers, a combination of creatinine and CysC is recommended, both for children [128] and adults [130]. There are problems with knowledge translation. In London, Ontario, it took years and intense collaboration with the clinical biochemists to introduce a cost-effective solution on the existing multi-analyzer platform with a turn-around time of 1 h [131].

Serum Cystatin C to Creatinine Ratio

It has been proposed to use a ratio of CysC and creatinine as a marker of disease. The concept evolved after noticing significantly elevated cystatin C to creatinine ratios during near-term pregnancy. There are conditions, such as the third trimester of pregnancy, where CysC increases but serum creatinine remains normal or even decreases due to hyperfiltration. Furthermore, CysC is heavily expressed in the placenta towards the end of pregnancy for unknown reasons. Investigators have proposed that serum CysC C/creatine ratio as a good estimate of kidney function in Korean children with CKD [132]. Others proposed the GFR CysC/GFR creatinine as a better estimate for children with CKD [133]. Children with solitary functioning kidneys have hyperfiltration and are at risk for CKD. The KIMONO Study determined the precision of eGFR formulas (two for creatinine and two for CysC) in children with a single kidney. These investigators recommended the combination of serum CysC/creatinine-based eGFR for children with solitary kidneys [134]. Age- and sex-specific reference intervals for serum CysC/creatinine ratio in healthy 0 to 18-year-old Chinese children have also been determined, noting that this ratio decreased with age and was higher in girls [135]. In this context, a concept of "shrunken pore syndrome" was developed [136], mainly characterized by a higher low molecular protein concentration compared to the level of GFR and creatinine. We are unaware of any histopathological confirmation of this "shrunken pore syndrome."

Beta Trace Protein (BTP)

Another potential surrogate marker for GFR measurement is BTP [138–140], a low molecular weight protein (MW 20-31 kDa) also known as prostaglandin D2 synthase (PGDS; prostaglandin H2 D-isomerase [EC 5.3.99.2]). BTP has traditionally been used as a marker for cerebrospinal fluid (CSF) leakage, as it represents approximately 3% of the proteins in the CSF [140, 141]. The availability of serum BTP for the measurement of eGFR is limited [142–144]. Although both brain and serum BTP are composed of an identical amino acid sequence, variations in molecular size can be attributed to differences in oligosaccharide structure and N-glycosylation. Serum and urine BTP have longer sugar chains and higher sialylation than BTP in the CSF [144].

Beta trace protein shares many of the features of CysC as a marker of GFR [93]. Priem et al. were the first to describe BTP as a new marker of GFR in the creatinine-blind range in 1999 [145]. We have previously described the history, indications, benefits, and limitations of BTP as a marker of GFR [141]. Some possible advantages of BTP over CysC are that it does not have a significant relationship with c-reactive protein (a marker of inflammation), is unaffected by body composition, adequately reflects GFR during the third trimester, and its concentration is not impacted by thyroid function [146]. In children and adolescents from London, Ontario, the reciprocal of BTP correlates strongly with both ^{99}Tc DTPA and ^{51}Cr EDTA measurements of kidney function (Fig. 2). Donadio had similar results with an excellent correlation coefficient of $r = 0.924$ for BTP [147]. Bökenkamp also demonstrated a good correlation between BTP and GFR. In fact, his study suggested that BTP has a better diagnostic sensitivity than CysC when GFR is mildly impaired [148]. Unlike CysC, which is strongly positively charged,

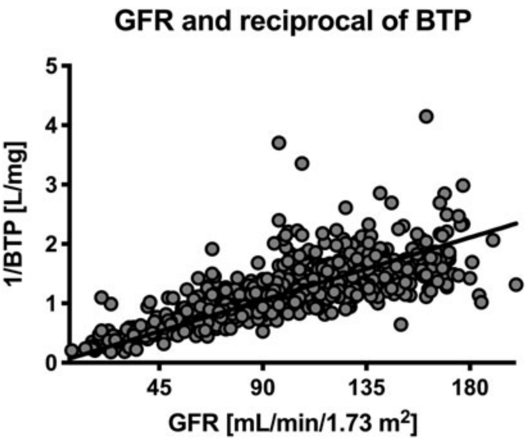

Fig. 2 The relationship of 1/BTP measured using the Siemens Healthcare BTP nephelometry assay in 825 Canadian children and adolescents aged 2–18 years of life with GFR measured using ^{99m}TcDTPA. Pearson r was 0.7102, 95% confidence interval 0.6745 to 0.7426, $p < 0.0001$

BTP has an isoelectric point of 5.5 or lower [149, 150]. BTP appears to be a more favorable marker in pregnancy [151] and in newborns [152]. Pediatric reference intervals have been published that include newborns and infants [153]. Formulae for the estimation of GFR based on BTP have been developed and validated for adults [143] and for children [138]. Leslie Inker published a study from the CKD-EPI dataset, using BTP and beta-2 microglobulin, which unlike creatinine or CysC did not show any differences due to sex [154]. However, this formula cannot be used for children [155].

Unfortunately, the availability of BTP is limited and the cost is quite high. Unlike for CysC and creatinine, there is no higher order reference material available to standardize the measurement. The two main assays by Cayman Chemicals (an ELISA method) and Siemens Healthcare (a particle-enhanced nephelometric immunoassay using polyclonal rabbit antibodies against human urinary BTP), use different analytical techniques and different antibodies, which may recognize different glycoprotein epitopes and therefore, may not bind to all BTP isoforms.

Beta-2 Microglobulin

Beta-2 microglobulin (B2M) is a low molecular weight protein (MW 11.8 kDa) and part of a class of major histocompatibility antigens expressed on the cell membranes of nucleated cells. B2M is freely filtered at the glomerulus, reabsorbed and catabolized in the proximal tubule by endocytosis [156, 157]. B2M is released into the systemic circulation during cell turnover and its volume of distribution is considered to be in the extracellular space. Bernier, Cohen, and Conrad were the first investigators who noted that serum levels of B2M were up to 150 times higher in patients with kidney disease of varying etiologies than those with normal kidney function [158]. In addition, these investigators found that serum B2M correlated with creatinine in patients with kidney failure [158]. Using rat animal models, B2M was injected intravenously in normal and ureter ligated rats and no B2M appeared in the urine while serum concentrations decreased promptly, indicating that B2M is catabolized in the kidney [159]. However, in the anephric rat model, the serum half-life of B2M was prolonged [159].

Viberti and his colleagues measured serum B2M, creatinine, and ^{51}Cr-EDTA GFR in patients with long-standing diabetes and noted a significant negative correlation between B2M and creatinine with measured GFR, respectively. B2M was always above the normal range when the GFR was <80 ml/min/1.73m^2, while serum creatinine was within the normal range in two patients, even when the GFR was ~65 ml/min/1.73m^2. Additionally, creatinine showed a diurnal variation, while B2M levels remained unchanged during the day, and was independent of food intake [160]. Jung and his colleagues studied different low molecular weight proteins and creatinine, correlating their levels to measured GFR by ^{99m}DTPA [161]. Although ribonuclease and B2M were more sensitive than creatinine in detecting low GFR, the large scatter of GFR confidence interval limits which corresponded to the upper reference limits of B2M and ribonuclease, made them less acceptable for GFR prediction [92, 161]. Nonetheless, B2M appears to be a good GFR estimator in unborn children with congenital obstructive uropathy [162].

B2M can be measured in urine and serum using various commercially available methods including particle-enhanced turbidimetric immunoassay (PETIA) [163], particle enhanced nephelometric immunoassay (PENIA) [164], or enzyme-linked immunosorbent assay [165]. The test results can vary, depending on the assay used. Despite reference materials from the World Health Organization (WHO) (1985) and the Institute of Reference Materials and Measurements (2015), commercial laboratories do not always follow these standards, resulting in variable results [166].

Increased B2M levels can be seen in infections, liver disease, lymphoproliferative disorders, malignancy, and inflammation [169–172]. Other non-GFR determinants associated with increased B2M levels include higher body mass index (BMI), hypertension, higher c-Reactive Protein, and lower HDL cholesterol. Unlike creatinine, B2M levels are less affected by age, sex, and race, but they are affected by smoking, and urinary protein excretion [171]. Corticosteroids decrease B2M [172]. Therefore, all of these factors should be taken into consideration when using B2M in calculating GFR, as they can cause bias and errors in GFR estimation.

Traditionally, elevation of B2M in CKD has been attributed to decreased filtration and decreased catabolism by the proximal tubule. However, recently, the role of uremic toxins in decreased binding of B2M to MHC molecules on the cell surface, resulting in increased shedding of B2M, is being postulated [173].

Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) investigators pooled the date from three large studies in adults with CKD where GFR was measured using urinary iothalamate [156, 176–178]. The goal was to develop equations using BTP, B2M alone, or in combination and to compare them to CKD-EPI creatinine and CysC-based equations. These equations were validated in the participants from these three studies. Some non-GFR determinants varied between CysC, creatinine, BTP, and B2M, while some were common. The combined B2M-BTP equation did not perform any better than the CysC or creatinine equation, and it was less accurate than the combined CysC-creatinine equation.

In children with various kidney diseases, these newer equations employing BTP and B2M were applied using post-hoc analysis of previously published data by Filler and collaborators. Although all the three newer GFR equations correlated significantly with the absolute GFR (not corrected for BSA), the confidence interval was large and unacceptable for the combined B2M-BTP equation. Thus, at this time, the combined B2M-BTP equation cannot reliably be used in children [155]. B2M has been measured in cord blood and can be used to estimate kidney function in fetuses with severe obstructive uropathy [100, 177].

Based on these studies, combining multiple endogenous markers of GFR with different non-GFR determinants, could potentially help in developing GFR equation(s) with minimal bias and increased precision; accounting for renal function level, race, sex, body surface area, and BMI, among other variables. It is also possible that with future studies different formulae will be used in different populations and health conditions.

Ferrocyanide

Ferrocyanide clearance is equal to the measured GFR in the dog, but in men it is lower. Miller and Winkler noted that ferrocyanide was reabsorbed by the tubules and its excretion did not provide accurate measurements of GFR in humans compared to dogs [178]. While several researchers explored this biomarker in other species, such as the cat, it has not been developed further as a GFR biomarker.

N,N,N-trimethyl-L-alanyl-L-proline betaine (TMAP)

This endogenous biomarker recently described as metabolite x17299 N,N,N-trimethyl-L-alanyl-L-proline betaine (TMAP) [179], belongs to the class of organic compounds known as dipeptides.

Like inulin, it is not charged. Its Monoisotopic Molecular Weight is 228.14 g/mol. These are organic compounds containing a sequence of exactly two alpha-amino acids joined by a peptide bond. Using untargeted metabolomics, Bradley Urquhart and his group recently identified TMAP as a new small molecule that appears to be a promising endogenous marker for the estimation of GFR [180]. This biomarker outperformed serum creatinine in over 400 non-dialysis CKD patients significantly, with an area under the receiver operated characteristics (AUROC) plot of 0.815; compared to an AUROC of 0.745 for creatinine. In dialysis patients, it demonstrated a stunning AUROC of 0.993 [180]. Currently, efforts to improve these methods are underway to validate this biomarker. Based on preliminary unpublished results, this novel biomarker has an excellent potential to estimate kidney function, which may not be afflicted with any of the setbacks of creatinine or low molecular weight proteins.

Formulae for the Estimation of GFR

A large number of formulae have been proposed for the estimation of GFR. Still, the Schwartz bedside formula [181] remains the most widely used formula. Today, we know that the combination of CysC and creatinine plus/minus urea, yields much more robust estimations of GFR. Table 2 lists commonly used GFR equations, of which the improved 2012 Schwartz formula using the combination of creatinine, CysC, and urea, probably performs best in children [128]. However, this formula requires additional information, such as height, which is often inaccessible to the laboratory information system. As a consequence, in London, Ontario, the old Filler formula [115] is used for the estimation of GFR in the clinical routine. To the best our knowledge, this formula remains the only formula validated for both adults and children and for GFR levels in the hyperfiltration range.

It should be highlighted that each formula performs best in the range where it was generated [182]. For instance, the CKD-EPI formula was generated from almost 4000 gold-standard nuclear GFR measurements; however, less than 1% of these were generated in young adults under 30 years of age. This may be the reason for the poor convergence of the 2012 Schwartz formula and CKD-EPI [183]. In that study of 18–30-year-olds, the 2012 Schwartz formula consistently estimated lower GFR values than the CKD-EPI formula, and they only converge at age 30 [183]. Selistre proposed to use pediatric formula for adolescents and young adults (AYA) up to 30 years of age [184].

Kidney Function Measurement and Interpretation in Special Health Conditions

As noted above, certain populations require special considerations for kidney function measurement and interpretation. In spina bifida and muscular dystrophy, only CysC should be used to measure kidney function. The abnormal muscle mass in both conditions always leads to an overestimation of GFR if creatinine is used. The Zappitelli [186] or Filler formula [115] are useful in these conditions [27]. Young athletes taking creatinine supplements would also benefit from a CysC-only approach [190]. In contrast, eGFR estimation using small molecular weight proteins should be avoided in patients with increased protein production such as hyperthyroidism [27]. We recommend the educational resource about GFR measurement for special populations in *Pediatric Nephrology* for a thorough review of dietary effects, inflammation, protein catabolism, altered muscle mass, sex, and conditions such as wasting conditions [27]. For some conditions, such as cystic fibrosis and chronic pseudomonas infections, only nuclear medicine methods may be reliable [191].

Age-Related Issues of Kidney Function Measurement

Neonates In pre-terms, renal development is interrupted, affecting nephron endowment [192]. Measuring serum creatinine in the first

Table 2 Commonly used GFR equations

Equation name	Equation
Equations with serum CysC and without serum creatinine or urea	
1. **Bökenkamp** [117].	GFR (mL/min/1.73 m^2) = 137/serum CysC – 20.4
2. **Filler** [115].	GFR (mL/min/1.73 m^2) = 10^(1.962+ (1.123 * LOG (1/serum CysC))
3. **Grubb** [185].	GFR (mL/min/1.73 m^2) = 84.69 * serum CysC $^{-1.68}$ x 1.384 for age < 14 y
4. **Zappitelli (CysC)** [186].	GFR (mL/min/1.73 m^2) = 75.94/[serum CysC 1.17] if renal transplant, x 1.2
5. **Schwartz improved 2012 (CysC only)** [128].	GFR (mL/min/1.73m^2) = (40.9 ± 0.3)*[1.8/CysC (mg/L)]$^{(0.931 \pm 0.020)}$
6. **Grubb standardized material 2014** [187].	GFR (mL/min/1.73 m^2) = 130*CysC$^{-1.069}$*age[years]$^{0.117}$–7
Equations with serum creatinine and without serum CysC or urea	
7. **Schwartz improved 2012 (Cr only)** [128].	GFR (mL/min/1.73m^2) = (42.3 ± 0.3)*((height (m)/SCr (mg/dL)))$^{(0.780 \pm 0.016)}$
8. **Pottel full age Spectrum formula** [188].	GFR (mL/min/1.73m^2) = 107.3/(SCr/Q) for ages 2–40 years GFR (mL/min/1.73m^2) = 107.3/(SCr/Q)*0.988$^{(Age-40)}$ for ages >40 years; where Q-values are the mean or median SCr value for age-sex-specific healthy populations.
Equations with serum urea and without serum CysC or creatinine	
9. **Schwartz improved 2012 (urea only)** [128].	GFR (mL/min/1.73m^2) = (41.0 ± 0.5)*[30/BUN (mg/dL)]$^{(0.613 \pm 0.024)}$
Equations with serum CysC and serum creatinine	
10. **Bouvet** [189]	[(SCr (μM)/96) $^{(-0.35\ (+/-0.20))}$]*[(CysC (mg/L)/1.2$^{(-0.56\ (\pm0.19))}$]*[(body weight (kg)/45)$^{(0.30\ (\pm0.17))}$]*[age (years)/14)$^{(0.40\ (\pm0.16))}$]
11. **Schwartz improved 2012** [128] **(CysC + Cr).**	GFR (mL/min/1.73m^2) = (41.6 ± 0.3)*((height (m)/Scr (mg/dL)))$^{(0.443 \pm 0.026)}$ *[1.8/CysC (mg/L)]$^{(0.479 \pm 0.031)}$
12. **Zappitelli (CysC + Cr)** [186].	GFR (mL/min/1.73 m^2) = (507.76*$e^{0.003*height}$)/ (CysC$^{0.635}$*SCr$^{0.547}$ [μmol/L]) If renal transplant, x1.165 If spina bifida, x(SCr$^{0.925}$ [μmol/L])/40.45
Equations with serum creatinine and serum urea	
13. **Schwartz improved 2012 (Cr + urea)** [128].	GFR (mL/min/1.73m^2) = (41.9 ± 0.3)* [(height (m)/Scr (mg/dL))]$^{(0.662 \pm 0.021)}$* [30/BUN (mg/dL)]$^{(0.171 \pm 0.021)}$
Equations with serum CysC and serum urea	
14. **Schwartz improved 2012 (CysC + urea)** [128].	GFR (mL/min/1.73m^2) = (40.8 ± 0.3)*[1.8/CysC (mg/L)]$^{(0.796 \pm 0.027)}$ * [30/BUN (mg/dL)]$^{(0.157 \pm 0.022)}$
Equations with serum CysC, serum creatinine, and serum urea	
15. **Schwartz improved 2012 (Cr + CysC + urea)** [128] .	GFR (mL/min/1.73m^2) = (41.5 ± 0.3)*((height (m)/Scr (mg/dL)))$^{(0.417 \pm 0.026)}$ *[1.8/CysC (mg/L)]$^{(0.431 \pm 0.032)}$ *[30/BUN (mg/dL)]$^{(0.088 \pm 0.019)}$

3 days of life reflects maternal levels in all neonates, regardless of gestational age [114]. Because of this shortcoming, CysC [152, 193] or beta-trace protein [194] offer more accurate estimates of neonatal kidney function. Another indirect measure of kidney function in this age group includes renal length by ultrasound images. In the pre-term, nephron endowment is compromised [18], and their muscle mass is decreased so their creatinine levels are lower. Full-term healthy neonates will begin to reflect recruit nephrons and serum creatinine will be reflective of actual levels by day three of life. If the neonate was exposed to adverse circumstances in–utero, such as maternal malnutrition (as in the Dutch cohort that formed the basis for the Barker Hypothesis/thrifty phenotype), medications (i.e., angiotensin-converting enzyme inhibitors), alcohol, and other substances, then their baseline level of renal function may not be accurate or represent steady-state levels.

Children and Adolescents Ages 1–18 Years The eGFR in this age group has been calculated by using the modified Schwartz formula, which multiplies the height in centimeters times a constant (0.43), divided by serum creatinine. The results reflects the GFR normalized to 1.73 m^2 [195]. The modified Schwartz formula corrects by surface area, but it does not correct for sex or race [195]. While this formula was developed from data of children with chronic kidney disease enrolled in the North American Chronic Kidney Disease in Children (CKiD) Study [196], it has also been used for healthy children and adolescents.

Transition-Age Period With the advent of electronic health records, young adults 18 years and older receive an automated creatinine-based eGFR calculation, based on the CKD-EPI formula. Unlike in their childhood and adolescence, 18-year-old individuals suddenly receive an eGFR calculation accounting for sex, race, height, or weight, and this may result in abrupt changes in renal function estimation [130]. With the CKD-EPI equation, patients may be subject to significant overestimation of eGFR, particularly Black patients.

In the USA, we performed a single-center study of longitudinal creatinine measurements in 18–30-year-old patients with CKD and determined that the 2012 Schwartz and CKD-EPI equations, exhibit poor agreement during this age period, particularly in males [183]. Concordance improved steadily as patients aged, and convergence occurred at age 30, but these differences were less dramatic for females. Our findings suggest that switching to the CKD-EPI equation after age 18, may not be an appropriate method for estimating renal function in AYAs with CKD [183]. As previously stated, Selistre et al. proposed to use the pediatric formula for adolescents and young adults [184]. Vice versa, adult formula such as the Cockcroft Gault formula, cannot be used in children and adolescents [197].

All Ages In cross-sectional samples from Europe and the USA, 6870 healthy Caucasian and those with kidney disease, ages 1–70 years (735 children), helped develop the “full age spectrum” equation, using isotope/tracer-measured GFR [188]. For CysC, only the old Filler formula appears to be validated for all ages and also for all ranges of GFR including hyperfiltration [115]. The CysC formula for GFR estimation works well for children [182]. The adult CKD-EPI formula came from three large studies in three continents combined, but there were few young adults included. A similar international multi-center approach is needed for all age groups as proposed by Björk et al. [198].

Race-Related Correction in Kidney Function

Race and ethnicity are sociological constructs, and while these terms have been used to describe health outcomes and disparities, they have no biological role. In fact, based on genomic studies, there are no biological differences by race. The inclusion of race in eGFR equations is being re-examined, as it does not reflect the correct level of kidney function among Black people. In adults, the 2009 Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equation includes a multiplication factor for race and Black patients had a 16% higher mean measured GFR when compared to matched sex, age, and serum creatinine of non-Black patients [199]. Similar findings were described using the MDRD equation [174]. Among preadolescents and adolescents, Martin reported that Black individuals excreted greater amounts of creatinine [200].

Using a multiplication factor for Black patients causes delays in referrals to nephrology care, in enlisting on transplant waiting lists, and it may affect drug dosing. Furthermore, there is no guidance about people with mixed race. On the other hand, removing the race factor could result in overdiagnosis of CKD or ESKD, and potentially lead to errors in drug dosing. In some Asian countries, other race-specific equations for eGFR among adults have been used [201]. Also, pediatric formulas may work better in a given setting. The new Schwartz equation was developed in a large USA population of patients with CKD with great predominance of patients with obstructive uropathy. This formula had poor performance in healthy Japanese children, particularly after 14 years of age [202]. Finally, race is not recorded in some jurisdictions. For instance, in Ontario, Canada, hospitals and large provincial healthcare databases do not record race in the medical record [203]. Some formulas using small molecular weight biomarkers such as CysC do not include race. At this point in time, it is unclear if corrections by race should be made. Pottel and colleagues made a strong pitch against the inclusion of race using population-normalized serum creatinine to develop the full age spectrum formula (see Table 2) [204].

Sex-Related Correction in Kidney Function and Disparities in Disease Progression

Whereas it is debatable if adjustments have to be made for race, or whether the poor performance of some formulae in different parts of the world is more related to the lack of international collaboration to establish a world formula; sex has to be considered when measuring kidney function. There are substantial sex differences for almost all biological scenarios. Females have less muscle mass as demonstrated in autopsy studies [205]. There is also a difference in the fat mass, especially during adolescence [206]. In the growing adolescent, there are differences in CysC levels by sex, as noted in the National Health and Nutrition Examination Survey [207]. In this third USA-representative study, cross-sectional CysC was higher in males (mean 0.84 mg/l), as well as in non-Hispanic White versus non-Hispanic Black and Mexican American adolescents ages 12–19. Furthermore, serum creatinine (mean 0.71 mg/dl) was also higher in males and lower in non-Hispanic Whites and Mexican Americans compared to non-Hispanic Black Americans. Furthermore, while creatinine increased with age, CysC levels decreased, particularly in females. Uric acid and blood urea nitrogen were significantly associated with CysC levels (adjusting for age, sex, and race/ethnicity) [207]. In a longitudinal sample of children and adolescents who underwent amalgam dental work in Lisbon, Portugal, the sex differences were not noted [208].

The decline in eGFR is greater among females compared to males, however, this may be explained by the CKD etiology, as females have more glomerular conditions compared to males, who have more congenital anomalies of the kidney and urinary tract (CAKUT) [209]. The disparities by sex in patients aged 2–19, continue at end-stage kidney disease. In the United States Renal Data System, 14, 024 pediatric patients started renal replacement therapy between 1995 to 2011, and girls had a greater risk of death or were less likely to receive a transplant in an adjusted analysis [210].

We analyzed the difference by sex when developing a BTP formula, comparing the correlation of creatinine with this small molecular weight protein [142]. Figure 3 shows the regression lines for the reciprocal of CysC, in adolescents with CKD (165 males and 155 females) aged 13–18 years. Whereas the slopes were similar, the elevations of the two regression lines were significantly different ($F = 18.90$, DFn = 1 DFd = 317, $p < 0.0001$, *unpublished data*).

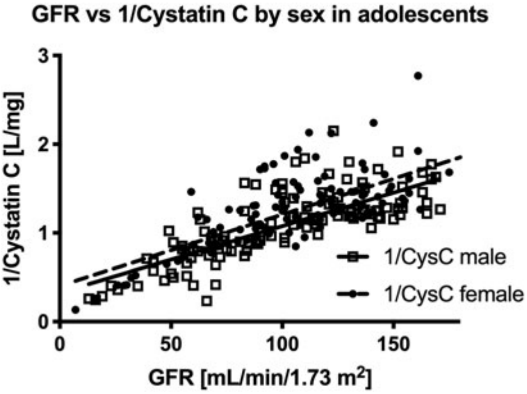

Fig. 3 The relationship between measured ^{99m}Tc DTPA GFR and the reciprocal of 1/Cystatin C in adolescents with chronic kidney disease (165 males and 155 females) age 13–18 years. Slopes were similar but the elevations of the two regression lines were significantly different, indicating the strong need for sex-specific formulae ($F = 18.90$, DFn = 1 DFd = 317, $p < 0.0001$)

Imaging for the Measurement of Kidney Function

Imaging has been proposed as an alternative for the assessment of kidney function. Magnetic resonance imaging (MRI) may serve as a good tool to assess interstitial fibrosis in kidney allografts [211]. Several authors, especially Abitbol from Miami, have advocated for using ultrasound-based renal volumes and renal volume z-scores for the assessment of kidney function [212]. This may work well for neonates in whom there is no hyperfiltration, however, there may be glomerular hypertrophy and an increase of the renal cortex, which masks decreased kidney function. Renal length z-score by ultrasound measurement in children with solitary functioning kidneys does not predict kidney function at 7 years of age (mean follow up of 5 years) [193]. In an elegant renal ultrasound study, it was shown that only the medulla, as a separate compartment, lags behind after premature birth [213]. Ultrasound images were obtained at 32 weeks, 37 weeks, and 6 months of age. Kidney volume, length, renal cortex and medulla thickness were measured and compared between preterm and term babies. Traditionally, it is even difficult to get renal volumes from radiologists. Kidney length or kidney volume z-scores are rarely reported, let alone reports of the differentiation of the volumes of the medulla and cortex. We have recently assessed the relationship between kidney length and kidney volume z-scores and found very poor agreement [215]. On the other hand, special CTs may evolve to become a tool for measuring both renal cortex and renal medulla blood flow, as we have recently shown when analyzing the impact of testosterone on renal function [212]. At this point in time, imaging is not yet well established as a tool for the measurement of kidney function; however, here is a great opportunity for future research.

Conclusions

Kidney function cannot be assessed directly and GFR is the best surrogate of renal function. The gold standard for GFR measurement is inulin clearance (ideally combined with simultaneous PAH clearance); however, this is no longer practiced in the clinical setting. Fortunately, there is good agreement with nuclear medicine methods such as ^{99}Tc iohexol ^{99}Tc DTPA, ^{51}Cr EDTA, and iothalamate. Iohexol and iothalamate can also be performed without radiolabeling.

Creatinine, albeit a marker afflicted with many technical problems, is the most commonly used endogenous biomarker of kidney function. CysC is a superior biomarker to measure kidney function and can be used even at 1 day of life, but its availability is limited. Currently, the best tool for estimation of GFR is the combination of CysC and creatinine measurements. Special populations require customized approaches for measurement and interpretation of kidney function. Future research may involve additional endogenous biomarkers, such as BTP, B2M, and TMAP. The role of imaging for the assessment of kidney function requires additional research.

Abstract

Diagnostic imaging is an essential component of the routine evaluation of children with kidney disease. Ultrasound, due to low cost and absence of side effects, is the most common modality, with special importance in evaluating a child with acute kidney injury or hematuria and diagnosing and following children with congenital anomalies of the kidney and urinary tract. Voiding cystourethrograms remain important for diagnosing vesicoureteral reflux and assessing the urethra, but radiation exposure can be reduced or eliminated in some patients via radionuclide cystography or contrast-enhanced voiding urosonography, respectively. CT, ideally with protocols that reduce radiation exposure, provides excellent anatomic resolution, with applications that include assessing children for renal artery stenosis and acute nephrolithiasis, and evaluating a child following trauma to the urinary tract. MRI provides excellent anatomical detail without radiation but is expensive and may require sedation in young children. Magnetic resonance urography enables determination of split differential renal function and transit time of contrast through the kidney, making it an effective technique for assessing hydronephrosis. A variety of nuclear medicine modalities are used to assess renal scarring, locate ectopic kidneys, decide if a hydronephrotic kidney is obstructed, locate a pheochromocytoma, and determine differential renal function. Retrograde urethrography, often utilized after trauma, evaluates urethral caliber and integrity.

Diagnostic Procedures

Imaging is essential for the diagnosis and management of many disorders of the urinary tract (UT). Clinicians should be familiar with the available techniques, including their indications, limitations, and potential complications [1, 2]. Ultrasound (US) is the most widely used modality because of the information provided, safety, and low cost. Intravenous pyelography (IVP) is currently seldom utilized, but voiding cystourethrography (VCUG) and nuclear medicine studies continue to have important roles. Computed tomography (CT) is readily available and can acquire images rapidly, generally obviating the need for sedation. Magnetic resonance imaging (MRI) generates anatomically precise images without radiation exposure, but at high direct financial cost and with the need for sedation in young children. Imaging studies should be carefully selected, with consideration of diagnostic utility, cost, and potential complications such as contrast nephropathy and radiation exposure (Table 1).

Ultrasound

US is the principal imaging modality for visualization of the UT. US provides a rapid assessment of kidney shape and size, and it is especially good at identifying hydronephrosis. Studies are completed without discomfort or sedation, and there are no known complications or side effects. In addition, US is relatively inexpensive and readily

From Viteri et al. [3]

available. The skill of the examiner can significantly influence the information obtained via US. Lack of patient cooperation and large body habitus may also limit image quality. Because of its low cost and the absence of side effects, US is the optimal modality for clinical situations requiring repeated evaluations. For example, US can assess hydronephrosis before and after an intervention such as a catheter, stent, or nephrostomy tube placement. US is also ideal as a screening examination for children who need surveillance for kidney stones or malignancy. Advances in sonographic technology including compound imaging, harmonic imaging, panoramic imaging, elastography, 3D imaging, and contrast-enhanced sonography/voiding urosonography have improved image quality and utility [3].

Technique

Images are generally obtained with the patient supine, which optimizes visualization of the upper poles, using the spleen and liver as acoustic windows. The contralateral decubitus position may permit better visualization in some patients. In certain situations, placing the patient in the prone position may allow for better visualization of the lower pole if subtle pathology is present. Ideally, the bladder should be visualized while filled with urine. A cooperative child should be asked not to void for a few hours prior to the exam. In a patient who is not toilet trained, the bladder should be visualized first to allow imaging of the bladder before the patient voids. US transducers produce sound waves of varying frequencies. High-frequency sound waves do not penetrate tissue as deeply but provide greater resolution. In most situations, the sonographer should use the highest frequency that penetrates to the desired depth. Hence, high-frequency US permits excellent resolution in infants and small children. Conversely, resolution is decreased in very large or obese individuals.

US evaluation of the UT should include measurement of renal lengths; assessment of renal shape, thickness and echogenicity of the cortex, and the presence of corticomedullary differentiation; and evaluation of the renal pelvis, ureters, and bladder. The ureters are not usually visible but may be seen when dilated due to underlying pathology. There are published standards for US determination of renal length for fetuses, preterm infants, full-term neonates, infants, and older children (Table 2) [4–9]. Length measurements should be made with the patient supine or in the contralateral decubitus position; length may be underestimated with the patient prone [10, 11]. Gestational age and birth weight correlate with kidney length in newborns [4, 7]. In older children, age is a convenient parameter, but length or height is a better predictor of normal kidney length [6, 12, 13]. A multivariable approach allows for improved prediction equations for renal length, including a web-based calculator [14]. In addition to renal length, normative values have been established for pediatric renal volumes and urinary bladder volumes (Figs. 1 and 2) [15].

Table 2 Renal length

Age	Mean length (cm)	Range (+/− 2 SD in cm)
Term newborn	4.48	3.86–5.10
2 months	5.28	3.96–6.60
6 months	6.15	4.81–7.49
1.5 years	6.65	5.57–7.73
2.5 years	7.36	6.28–8.44
3.5 years	7.36	6.18–8.54
4.5 years	7.87	6.87–8.87
5.5 years	8.09	7.01–9.17
6.5 years	7.83	6.39–9.27
7.5 years	8.33	7.31–9.35
8.5 years	8.90	7.14–10.66
9.5 years	9.20	7.40–11.00
10.5 years	9.17	7.53–10.81
11.5 years	9.60	8.32–10.88
12.5 years	10.42	8.68–12.16
13.5 years	9.79	8.29–11.29
14.5 years	10.05	8.81–11.29
15.5 years	10.93	9.41–12.45
16.5 years	10.04	8.32–11.76
17.5 years	10.53	9.95–11.11
18.5 years	10.81	8.55–13.07

Adapted from Rosenbaum et al. [9]

In adults and children, the average left kidney is slightly longer than the average right kidney [6, 7, 12], although this is only observed in slightly more than 50% of measurements of individual patients (the remainder have kidneys of equal length or a longer right kidney) [13]. In infants and adults, the median left renal length is about 3 mm longer than the median right renal length [6, 16]. In adults and older teenagers, males have longer kidneys, correlating with their increased height compared to females. Black children have shorter kidneys than white children [17]. Measurement of renal length in children has a fairly high rate of intraobserver and interobserver variation [18]; hence, US measurement of renal length lacks the accuracy to allow assessment of renal growth over limited time periods. Measurement of the left kidney length is less accurate, probably because the spleen provides a smaller acoustic window than the liver. Nevertheless, renal length discrepancy in children can be used to predict abnormalities on technetium 99m-dimercaptosuccinic acid (^{99m}Tc-DMSA) renal scintigraphy [19].

The appearance of the kidneys changes with age. The relative volume of medullary tissue compared to cortical tissue is increased in neonates and infants (Fig. 3a) [20]. Cortical echogenicity is increased in the term newborn kidney, with the majority having the same echogenicity as the liver or spleen [8]. Renal cortical echogenicity is further increased in premature infants, with some kidneys having cortical echogenicity greater than the echogenicity of the liver or spleen [21]. Cortical echogenicity decreases after birth, and only a small percentage of normal kidneys of term infants have cortical echogenicity equivalent to the liver or spleen by 6 months. Cortical echogenicity is compared to the liver or spleen, but this comparison may not be valid if there is underlying liver disease. Transient

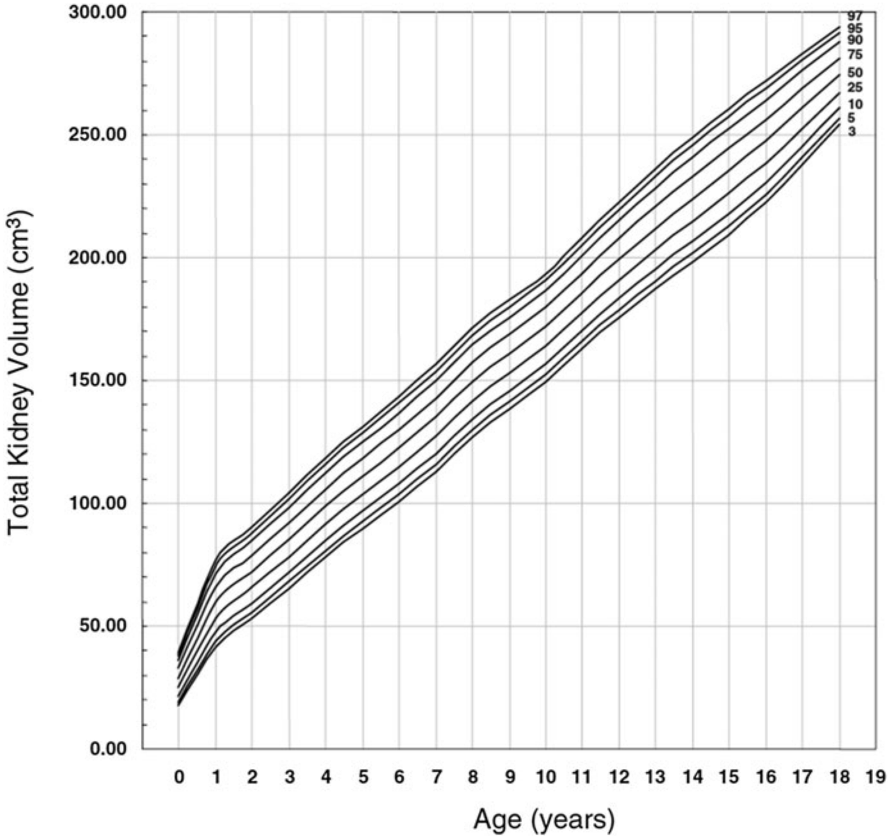

Fig. 1 Smoothed centiles of total kidney volume (length × width × depth × 0.523) in 3,376 children. (From Leung et al. [15])

increased cortical echogenicity of the kidneys may occur in children with a variety of nonrenal illnesses [22]. The kidneys of term newborns have prominent medullary pyramids that are relatively hypoechoic [20]. This results in marked corticomedullary differentiation. The echogenicity of the medullary pyramids increases after birth, and prominent medullary pyramids are not normally present by 1 year. In contrast, the central sinus echo is minimal at birth and gradually increases during the first 10 years of childhood (Fig. 3b, c) [8].

Hydronephrosis may indicate obstruction or vesicoureteral reflux (VUR), or it may be a normal variant, especially when mild. Several classification systems for hydronephrosis exist, including the Society for Fetal Urology grading system, as well as the Urinary Tract Dilation (UTD) grading system for hydronephrosis [23]. The Society for Fetal Urology grading system for hydronephrosis is predictive of the presence or absence of obstruction (Table 3) [24, 25]. Mild hydronephrosis is common in newborns and occurs in a higher percentage of males than females [26]. The UTD grading system was devised to provide more uniformity in nomenclature, have a more consistent means of classifying prenatal/postnatal urinary tract dilation, and to provide an algorithmic approach to postnatal management [23].

An increase in bladder wall thickness may be an indication of pathology, especially chronic increased bladder pressure. Measurement of bladder wall thickness is highly dependent on the degree of bladder filling, with some variation based on location of measurement, body mass index, and age [27]. The upper limit of normal is 5 mm for an empty bladder and 3 mm for a well-distended bladder [28]. US can be used to accurately estimate bladder volume [29, 30]. US

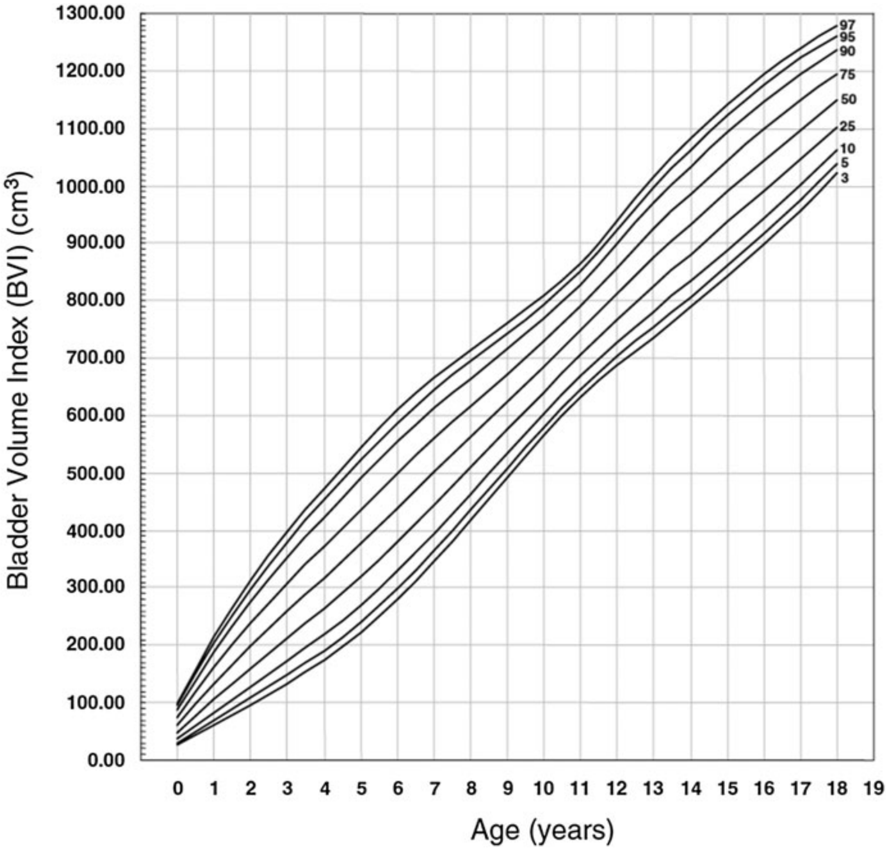

Fig. 2 Smoothed centiles of bladder volume index (length × width × depth) in 3.376 children. (From Leung et al. [15])

measurement of bladder volume after voiding is a useful parameter for assessing bladder function. US may detect ureteroceles or bladder masses.

Doppler US permits evaluation of blood flow and has been utilized to identify renal artery disease, renal vein thrombosis, tumor thrombosis in the renal vein and inferior vena cava, and arteriovenous fistulas [31, 32]. Resistance to blood flow can be quantified by measuring the resistive index (RI), which is calculated from the formula: RI = (peak systolic velocity-end diastolic velocity)/peak systolic velocity. A normal RI is below 0.7 in adults and children who are 6 years of age or older, but higher values are observed in children less than 6 years [33]. Power Doppler mode allows increased sensitivity for blood flow detection but does not provide information on flow direction or velocity. Power Doppler US is superior to color Doppler US in detecting intrarenal blood flow [34] and in identifying areas of decreased perfusion within the kidney [35]. Power Doppler increases the sensitivity of US for detecting acute pyelonephritis [36]. Power Doppler is very sensitive to motion artifact; hence, the requirement for a very cooperative patient limits its utility in young children. 3D US of the kidneys can also be performed, with subtraction of a dilated collected system in order to calculate renal parenchymal volumes [37].

Alternative sonographic techniques include contrast-enhanced US (CEUS) and contrast-enhanced voiding urosonography (CEVUS), each of which requires scanners that have a contrast imaging package/mode and administration of an US contrast agent consisting of microspheres containing an inert gas [38]. CEUS requires the contrast agent to be administered intravenously and can be used to assess perfusion of both native

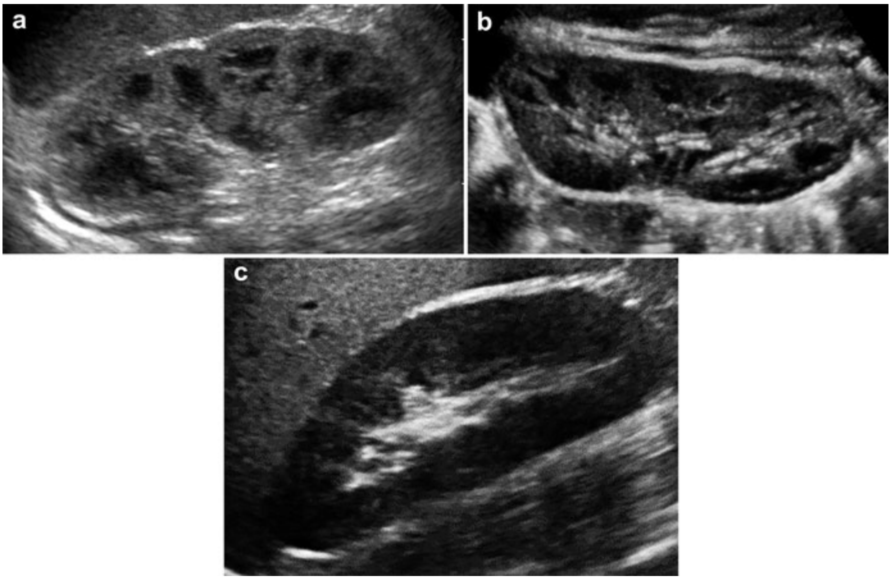

Fig. 3 (**a**) Normal ultrasound of a neonatal kidney. Medullary pyramids are hypoechoic with a relatively thin cortex. (**b**) Normal 2-year-old kidney. (**c**) Normal 16-year-old kidney. Note decreasing cortical echogenicity, decreased conspicuity of medullary pyramids, and increased renal sinus fat echoes with increasing age

Table 3 Society of Fetal Urology grading system for hydronephrosis

Grade	Ultrasound
0	No hydronephrosis
1	Only renal pelvis is seen
2	Renal pelvis and a few calices are seen
3	Virtually all calices are seen
4	Similar to grade 3, but parenchymal thinning present

and transplanted kidneys [3]. CEVUS is an alternative technique for detecting VUR that uses intravesical instillation of the US contrast agent [39–41]. The principal advantage is the elimination of radiation exposure, but bladder catheterization is still necessary. The results with VUS correlate well with conventional VCUG [40, 42, 43] and the technique can be used to image the urethra [3, 41].

Application

US is the initial imaging modality in a variety of clinical situations, including evaluation of renal failure, kidney transplant dysfunction, hematuria, screening for renal malignancy, abdominal mass, and follow-up of abnormal prenatal US. Procedural applications of US in pediatric nephrology include pre-biopsy or real-time localization of native and transplant kidneys and venous localization prior to hemodialysis catheter placement [44].

Voiding Cystourethrography

VCUG is the gold standard for the diagnosis of VUR. Most clinical studies of VUR have utilized VCUG. Moreover, VCUG is the only modality that detects VUR and provides detailed information about the bladder and urethra. Radiation exposure is the most important side effect of VCUG. Over the last several years, the radiation dose has been reduced through technological innovations, and a variety of additional approaches are available to further reduce radiation exposure [45–47]. A known allergy to contrast material is a contraindication to the study [48]. Because of the need for catheterization, VCUG creates a small risk of iatrogenic infection and trauma to the urethra, although these risks are low [49]. In addition, many children and families find catheterization frightening and emotionally traumatic. Sedation with midazolam appears safe and effective [50].

Technique

VCUG is done using fluoroscopy. An initial film prior to bladder catheterization detects calcifications or bony abnormalities; an abnormal bowel gas pattern may suggest a mass. The bladder is sterilely catheterized using a feeding tube (5 F in young infants; 8 F in older children), and urine can be obtained for culture. After emptying the bladder of urine, contrast material is infused to fill the bladder based on estimates of bladder capacity, but using gravity to avoid overfilling. The bladder must be filled to capacity to insure an adequate study. An early film during filling of the bladder is useful for identifying filling defects, such as caused by a ureterocele or bladder tumor. Films are taken before and after voiding, with VUR graded based on the International Reflux Study in Children [51]. In young children, who may not allow their bladder to fill to capacity, the sensitivity of VCUG for detecting VUR improves with multiple cycles of bladder filling and voiding [52, 53], but this increases the length and radiation exposure of the procedure. A film during voiding permits visualization of the urethra and is essential in male children to assess for posterior urethral valves (Figs. 4 and 5). At the end of voiding, a final film identifies residual urine and previously unidentified VUR. Technological advances including digital fluoroscopy with pulsed fluoroscopy and last-image-hold options have made it possible to diminish radiation dosage [54].

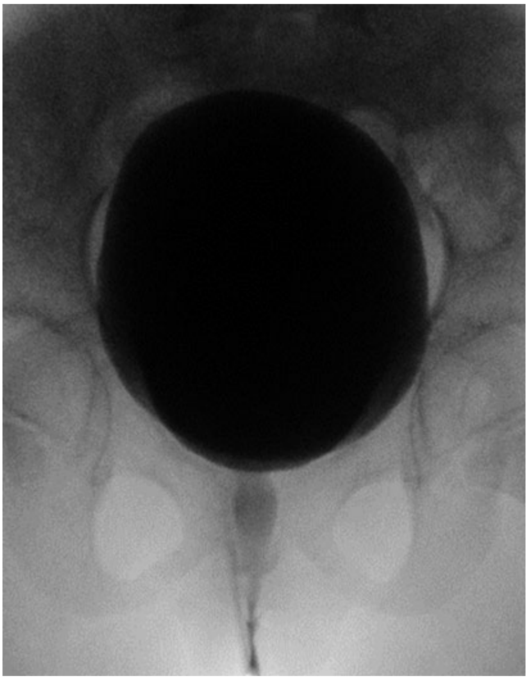

Fig. 4 Voiding cystourethrogram. Frontal voiding image of normal 5-year-old girl

Intravenous Pyelography

The availability of US and other imaging modalities such as MR urography has dramatically decreased the use of intravenous pyelography (IVP). The risks of IVP include radiation and contrast exposure; intravenous (IV) access is necessary.

Technique

An initial supine film is performed prior to contrast injection. Approximately 5–7 min after contrast, a film centered on the kidneys allows visualization of the nephrogram and the calices. Subsequent films are full length and taken 15 min and 30 min after injection. Delayed films are useful in cases of urinary obstruction. Bowel preparation does not improve image quality, although a short fasting period is usually recommended. The radiation exposure of IVP can be reduced by adjusting the number of films based on the clinical question and the results of initial films. Nonionic contrast medium improves image quality and decreases the risk of contrast nephropathy.

Application

Poor renal function limits the utility of IVP due to inadequate contrast accumulation in the kidneys. Moreover, poor renal function increases the risk of contrast nephropathy. IVP is currently rarely used in the evaluation of obstructive disease; US and nuclear medicine studies are the preferred imaging modalities. ^{99m}Tc-DMSA has replaced IVP for detection of renal scarring. IVP is useful for evaluation of ectopic ureters, ureteroceles, and fusion anomalies, although alternative imaging (US, MRI, CT) is generally utilized when available.

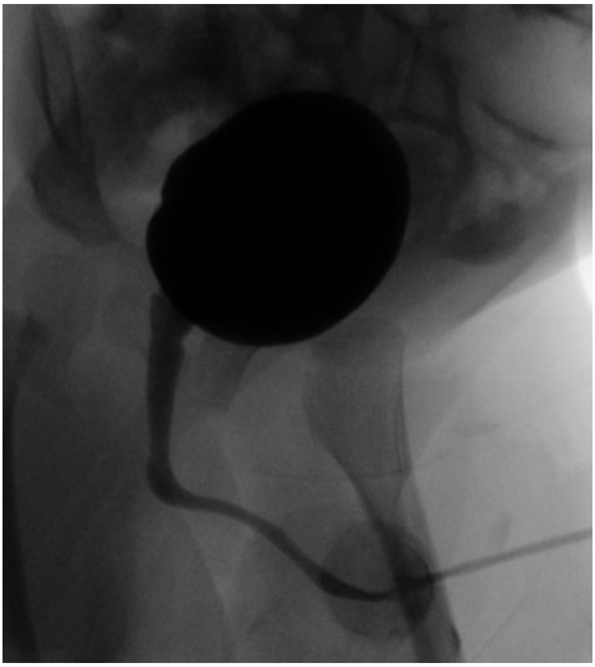

Fig. 5 Voiding cystourethrogram. Oblique voiding image of a normal 1-year-old boy

Retrograde Urethrography

Retrograde urethrography (RUG) is performed to evaluate urethral caliber and integrity, frequently following trauma [55].

Technique

Following advancement of a balloon microcatheter through the urethral meatus, the balloon is insufflated and iodinated contrast material is injected. The exam is typically performed fluoroscopically, but can be performed using convention radiography when needed [55].

Application

RUG is most frequently performed following perineal/pelvic injury, when there is concern for traumatic urethral injury, characterized by contrast extravasation (Fig. 6). The technique can also be used to evaluate for urethral stricture [55].

Computed Tomography

CT provides excellent anatomic resolution of the UT (Fig. 7) and has many applications. Radiation exposure is an important risk of CT and should limit its use to cases where the detail provided outweighs the risk of the study. IV contrast is necessary for optimal studies in most situations. Multiple strategies and innovations have reduced the radiation dose with CT [56, 57], but it remains an important concern. Sedation is currently rarely necessary due to rapid image acquisition, which also decreases motion artifact [58].

Technique

Thin-section helical imaging, now performed on all CT scanners, allows for multiplanar reformatted images to be obtained quickly and displays the kidneys, ureters, and bladder in three planes. Oral contrast, while often unnecessary for evaluation of the UT, is useful for examinations where differentiating bowel from pathology is necessary. Time constraints (acute trauma) or risk of aspiration may prevent the use of oral contrast. For younger children, excessive movement can be prevented by using blankets or adhesive tape. IV contrast is usually indicated, with the notable exception of nephrolithiasis evaluation. Low osmolality nonionic contrast is preferred; contrast is dosed based on weight. Neonates and infants require a longer delay from contrast injection to imaging.

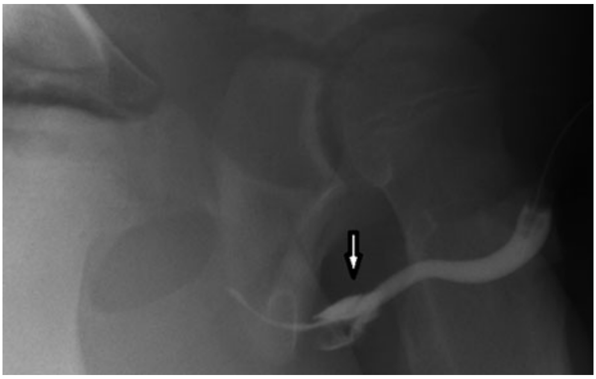

Fig. 6 Retrograde urethrogram of 10-year-old male following handlebar injury to perineum. Note urethral extravasation (arrow)

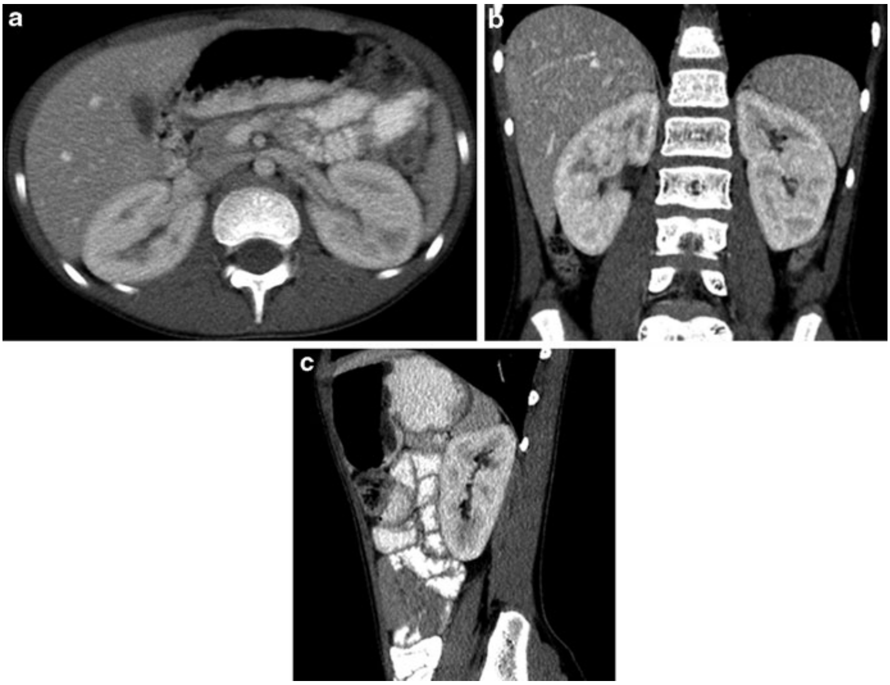

Fig. 7 CT of a normal 11-year-old boy. (**a**) Axial image through the midpole of both kidneys. (**b**) Coronal image. (**c**) Sagittal image

Application

CT is the most sensitive modality for initial evaluation of possible symptomatic nephrolithiasis, although US is generally utilized for surveillance to minimize radiation exposure. CT is used for renal tumor staging and is the optimal modality when trauma of the UT is suspected. CT provides excellent resolution of renal scarring, but ^{99m}Tc-DMSA is more commonly used. CT angiography is useful in assessing for renal artery stenosis [59]. Diminishing radiation exposure by using age- or weight-based exposure parameters and by limiting the field of view is suggested. Efforts should be made to achieve the lowest radiation dose needed in order to generate a diagnostic exam [56, 57].

Nuclear Medicine

A variety of radiotracers are utilized for imaging of the UT [2, 3]. The radiotracers emit photons, which are detected by a scintillation detector. Nuclear medicine imaging does not provide anatomic detail, but rather functional data that is typically utilized to answer a specific question. Nuclear medicine is often a complementary technique to imaging that provides structural information. While there is radiation exposure, it is less than other modalities such as VCUG, IVP, or CT. Glomerular filtration rate can be measured following the injection of a radiopharmaceutical and is discussed in detail in Chapter 21 [60].

Technique

Dynamic Renal Scintigraphy

Technetium 99m-diethylene triamine pentaacetic acid (^{99m}Tc-DTPA) and technetium 99m-mercaptoacetyltriglycine (^{99m}Tc-MAG$_3$) are the radiotracers currently utilized for dynamic renal scintigraphy. ^{99m}Tc-DTPA is primarily excreted via glomerular filtration; it is not reabsorbed or secreted by the tubules; its clearance is slightly lower than inulin. ^{99m}Tc-MAG$_3$ is predominantly excreted via tubular secretion. For most indications, ^{99m}Tc-MAG$_3$ is superior to ^{99m}Tc-DTPA because ^{99m}Tc-MAG$_3$ is more rapidly excreted and thus provides a better renal/background ratio. The nuclear radiotracers have a lower allergic reaction profile than radiographic contrast media [61].

Patients are encouraged to consume liquids immediately prior to the procedure as this facilitates exam interpretation and decreases the radiation dose to the urinary bladder [62]. Patients should ideally void before injection of isotope. The uncooperative child should be immobilized, but sedation is rarely necessary. Images are obtained with the patient supine; the scintillation detector is below the patient for native kidneys and above the patient for renal allografts. After bolus injection of radiotracer, dynamic images are recorded for 30 min. The initial images assess renal perfusion and later images evaluate excretion. Differential renal function is calculated using the early images, typically during the second minute, prior to radiotracer appearance in the collecting system.

Diuresis scintigraphy is performed to evaluate a patient for renal obstruction [63, 64]; use of a diuretic is only necessary if radiotracer does not rapidly drain from the renal pelvis during initial imaging. A dilated renal pelvis that is not obstructed may have slow drainage of radiotracer due to the increased pelvic volume. Administration of diuretic allows differentiation of an obstructed kidney from a non-obstructed dilated renal pelvis. Furosemide is given 15–20 min after administration of radiotracer, after which radiotracer drains rapidly from a non-obstructed renal pelvis (Figs. 8 and 9). Conversely washout of radiotracer is limited if obstruction is present; a half-life of radiotracer disappearance greater than 20 min indicates obstruction [65]. Test results and histological changes correlate well [66], and the test is sensitive and specific [65, 67]. Diuresis

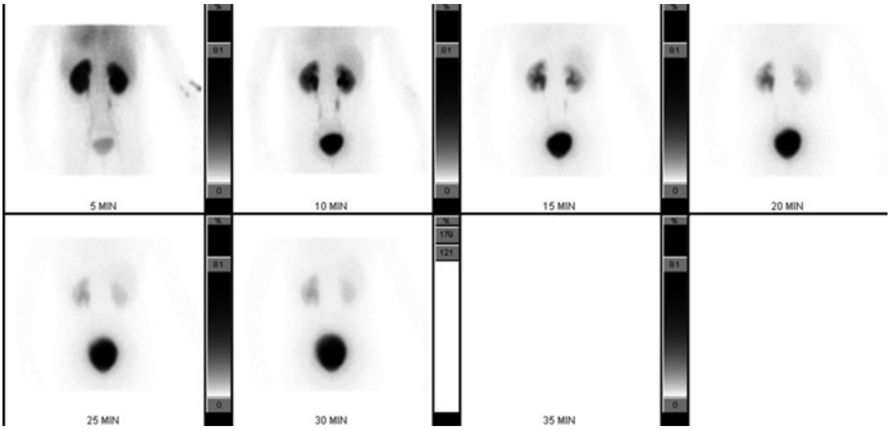

Fig. 8 Posterior image of a normal ^{99m}Tc-MAG$_3$ renal scan in an 8-year-old with hydronephrosis by ultrasound

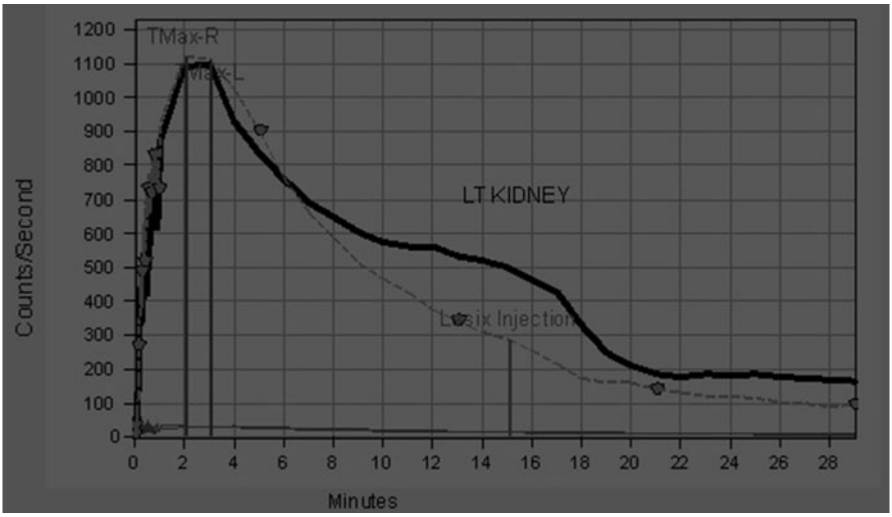

Fig. 9 Time-activity curve from ^{99m}Tc-MAG$_3$ renal scan showing symmetric prompt excretion of radiotracer, indicating no obstruction

scintigraphy is accurate in newborns, despite their lower glomerular filtration rate [67, 68], although follow-up imaging of normal results is necessary to ensure that obstruction does not subsequently develop [69]. Potential causes of false-positive results are a massively dilated renal pelvis or a kidney with very poor function [70], although technical modifications may allow for more accurate assessment of a poorly functioning kidney [71, 72]. False-positive results can also be decreased by obtaining images after the patient voids to avoid bladder pressure effects and after placing the child in the erect position to maximize gravitational drainage [73, 74].

Cortical Scintigraphy

^{99m}Tc-DMSA is the preferred radiotracer for imaging of the renal cortex [75]. ^{99m}Tc-DMSA is taken up by the cells of the proximal tubule, where it binds to sulfhydryl groups (Fig. 10). The accumulation of ^{99m}Tc-DMSA in the kidney is relatively slow; hence, imaging is typically performed 1.5–3 h after injection, although diagnostic accuracy may improve with an increased delay in imaging if renal function is significantly impaired. Posterior and left and right posterior oblique views should be obtained, although loss in diagnostic accuracy is minimal if only a posterior view is possible in a restless child [76]. Anterior imaging is preferred for pelvic or horseshoe kidneys. Additional pinhole images are useful for improving resolution when imaging infants.

A variety of factors may complicate interpretation of ^{99m}Tc-DMSA imaging. Fetal lobulations may give the false impression that there are areas of decreased radiotracer uptake. The splenic impression explains flattening of the superolateral surface of the left kidney [77]. The poles of normal kidneys may have relatively decreased uptake of radiotracer. Interobserver agreement in the interpretation of ^{99m}Tc-DMSA scans for scarring and acute pyelonephritis varies between studies [78–80]. ^{99m}Tc-DMSA is not specific for scars or acute pyelonephritis. Alternative explanations for defects such as cysts, hydronephrosis, infarcts, masses, or a dysplastic half of a duplex kidney can only be identified using alternative imaging strategies (e.g., US). Children with proximal tubulopathies have decreased uptake of ^{99m}Tc-DMSA and increased urinary excretion [81].

Single-photon emission computed tomography (SPECT) is an alternative to planar scintigraphy. SPECT appears to offer superior sensitivity for detecting renal scars [82, 83], although with a higher rate of false-positive results [84, 85]. The clinical relevance of the increased detection of small scars via SPECT is not clear. An intrarenicular septum, a common normal variant,

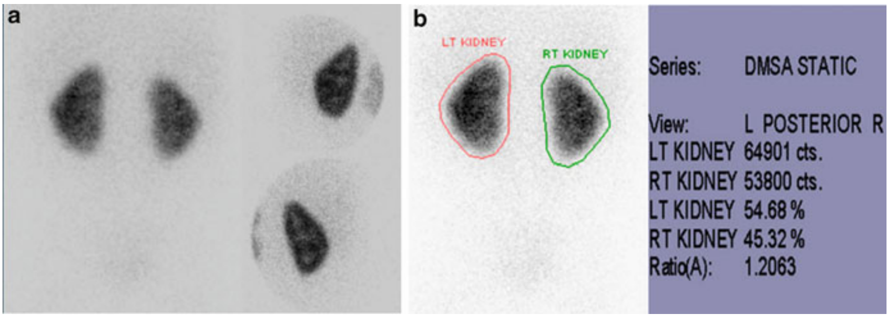

Fig. 10 (**a**) Posterior image and coned oblique images of normal kidneys on DSMA scan in a 3-year-old with a urinary tract infection. (**b**) Regions of interest drawn for split-function calculation

may lead to a photopenic area with SPECT, but can be differentiated from a scar because of preserved cortical uptake [86]. The increased imaging time required with SPECT may necessitate sedation in young children.

Split function is determined by outlining the appropriate regions of the kidneys and subtracting the activity of an appropriate background area in the posterior image. Normal split function is 50 % +/– 6 %. Estimates of split function must be corrected for attenuation if there is an anteriorly placed ectopic kidney. Such correction is not accurate with a pelvic kidney due to the effect of the pelvic bone. Imaging may need to be delayed for up to 24 h in an obstructed kidney because isotope accumulation in the renal pelvis may cause an error in estimating split function, with an overestimation of the function of the obstructed kidney if the image is obtained prematurely. A similar approach may be necessary for a non-obstructed, severely dilated renal pelvis, although injection of furosemide, with the subsequent diuresis clearing radiotracer from the dilated pelvis, is an alternative strategy. Estimates of split function are reliable, with good interobserver agreement, except in cases where renal function is significantly impaired [87].

Adrenal Gland Scintigraphy

Metaiodobenzylguanidine (MIBG), when labeled with either ^{131}I or ^{123}I, is used for the detection of catecholamine-secreting tumors, including pheochromocytomas and neuroblastomas [88]. MIBG, a guanethidine analog that structurally resembles norepinephrine, is taken up by sympathetic nerve cells. The patient should receive oral nonradioactive iodine before and after administration of radiolabeled MIBG to compete with free radioactive iodine, minimizing radioactive exposure to the thyroid gland. A variety of medications interfere with MIBG uptake into tissue and should be discontinued prior to MIBG imaging (Table 4). MIBG radiotracer is injected and images are obtained at various times depending on the isotope. MIBG accumulates in a variety of organs, including the liver, heart and salivary glands; isotope is detected in the kidney and bladder due to renal excretion. Tumors can be identified because of the stronger radiotracer uptake, which is typically focal. ^{123}I has a much lower radiation burden than ^{131}I and results in superior images [89].

Radionuclide Cystography

Radionuclide cystography (RNC) is an alternative to VCUG for the detection of VUR (Fig. 11) [3, 90]. In RNC, a catheter is placed into the bladder, and a solution containing a radioisotope is infused, with complete filling of the bladder. Since it allows for continuous monitoring, RNC is

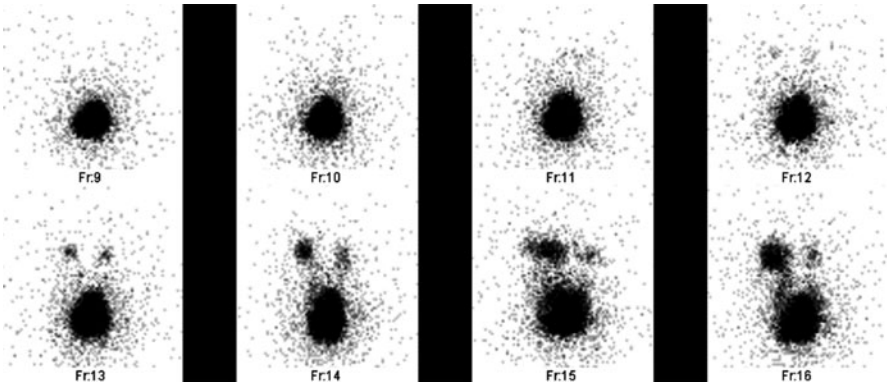

Fig. 11 Radionuclide cystogram. Posterior serial 10 s/frame images from a nuclear cystogram in a 4-year-old demonstrating bilateral vesicoureteral reflux

more sensitive at detecting VUR than VCUG, which cannot utilize continuous monitoring due to radiation concerns. Furthermore, the radiation burden with RNC is considerably less than VCUG. However, radionuclide cystography does not permit evaluation of the bladder or the urethra.

Applications

^{99m}Tc-DMSA is the preferred radiopharmaceutical for evaluation of the renal cortex and the gold standard for the identification of pyelonephritis and renal scars [62]. ^{99m}Tc-DMSA can be utilized to determine split renal function and to identify and characterize renal infarcts or anatomically abnormal kidneys such as horseshoe kidneys, pelvic kidneys, and crossed fused ectopia [91, 92]. Dynamic renal imaging with ^{99m}Tc-MAG$_3$ or ^{99m}Tc-DTPA permits evaluation of renal blood flow, split renal function, kidney location, and urinary drainage. Dynamic renal imaging allows determination of whether hydronephrosis is secondary to renal obstruction or an alternative etiology such as VUR, high urine flow, or relieved obstruction [93]. Dynamic renal imaging can be utilized to determine split renal function.

Magnetic Resonance Imaging

MRI, with its ability to image the abdomen in multiple planes and with sequences showing different signal characteristics, provides excellent resolution of the UT without radiation exposure (Figs. 12 and 13) [94]. Faster MR sequences allowing for rapid image acquisition, and the continued trend in reducing radiation exposure in the pediatric population have also increased imaging of the urinary tract by MRI [54]. Gadolinium-based contrast at standard doses is significantly less nephrotoxic than iodinated contrast [95], but gadolinium-based contrast is nephrotoxic when used at radiographic doses for angiographic procedures [96, 97]. Gadolinium-based contrast is also the dominant risk factor for the development of nephrogenic systemic fibrosis (NSF) [98], an entity that occurs almost exclusively in patients with end-stage kidney disease or severe renal impairment. Most cases of NSF have been associated with gadodiamide, although other gadolinium-based contrast agents may lead to NSF [99]. Gadolinium-based contrast should be used cautiously in patients with moderate to severe renal impairment [100]. Sedation is typically necessary for infants and young children. MRI is the most expensive imaging modality, but it may replace multiple other studies and provide superior resolution in certain clinical situations.

Technique

Magnetic resonance urography (MRU) provides superb anatomic detail combined with functional information [101]. In this technique, patients receive IV hydration and an IV gadolinium chelate (Gd-DTPA). The kidneys are imaged over time, allowing for a dynamic evaluation of renal

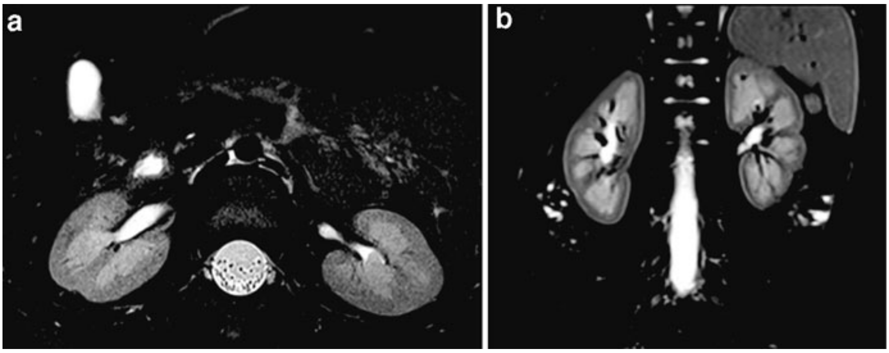

Fig. 12 Renal MRI of a normal 5-year-old. (**a**) Axial T2-weighted image through the midpole of the kidneys. (**b**) Coronal T2-weighted image

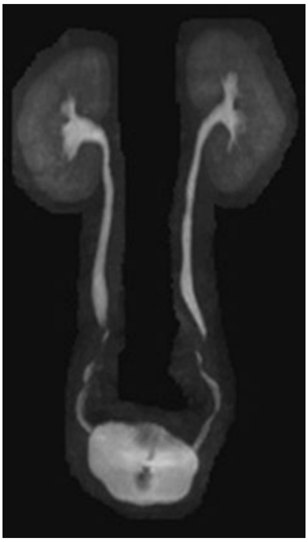

Fig. 13 Renal MRI. 3-D image of the kidneys and ureters in a normal 12-year-old

enhancement and drainage. In addition to anatomic assessment of renal parenchyma and collecting system anatomy, post-processing of MRU data derived from the study allows for determination of split differential renal function, transit time of the contrast agent through the kidney, and an estimate of glomerular filtration rate. MRU has superior contrast and temporal and spatial resolution when compared to renal scintigraphy [3, 54].

Application

Conventional MRI is useful in characterization of solid and cystic renal masses, renal vascular disease, and congenital abnormalities, including lower urogenital tract malformations and complex post-traumatic conditions [102–104]. The most common indication for MRU is hydronephrosis. This technique allows for simultaneous anatomic and physiologic assessment of the parenchyma, collecting system, and surrounding tissues [54, 105]. The goal of the exam is to determine whether the hydronephrotic kidney is obstructed based on its response to a fluid/diuretic challenge [101, 106].

Congenital Kidney and Urological Disorders

Fetal Imaging

The widespread use of fetal US has led to a dramatic increase in postnatal imaging of the UT. Most congenital abnormalities of the UT are now detected prenatally; this has led to a decrease in the diagnosis of obstructive uropathies as a consequence of urinary tract infection (UTI), potentially diminishing the need for renal US in children with UTI [107]. Fetal kidney length relates to gestational age (see Table 5) [5]. Fetal US is excellent at identifying hydronephrosis, which may identify infants with UT obstruction or VUR. Oligohydramnios, which may indicate poor urine output due to renal insufficiency, is easily quantified and followed. Persistent oligohydramnios is associated with pulmonary hypoplasia. The fetal bladder, which may be distended with impaired bladder emptying, and

41	4.5	0.3	3.9–5.1	4

Gestational age is an average of the gestational ages in weeks determined on the basis of biparietal diameter, femoral length, and abdominal circumference. *cm* centimeters, *SD* standard deviation, *CI* confidence interval; *n* number of fetuses. From Cohen HL et al. [5]

the echogenicity of the renal parenchyma are also visualized via fetal US.

Hydronephrosis is the most common renal abnormality on fetal US, and ureteropelvic junction (UPJ) obstruction is the most common pathologic condition, although a high percentage of kidneys are ultimately diagnosed as normal [108]. A postnatal US done in the first few days of life to follow-up on prenatal hydronephrosis often yields a false negative result, presumably because of low urine output due to physiologic dehydration [109]. Hence, the initial postnatal US should be done at least 4 weeks after birth or the child should have a second US if an early postnatal US is negative. Deferral of the initial US is inappropriate if the prenatal US suggests the presence of disease that would require immediate intervention (e.g., bilateral hydronephrosis or oligohydramnios). The degree of prenatal hydronephrosis is highly predictive of the likelihood of pathology on postnatal evaluation [110].

Prenatal US can detect children with a variety of other pathologic conditions, including posterior urethral valves, multicystic dysplastic kidney, VUR, megaureter, duplex anomalies of kidneys with upper pole hydronephrosis, single kidney, polycystic kidney disease, and Eagle-Barrett syndrome [111]. While fetal US remains the primary means of *in utero* imaging, fetal MRI has a role in further characterization of complex fetal genitourinary abnormalities. The pregnant patient is most frequently scanned in the supine position during the second or third trimester. IV contrast material is not used for the exam. The most commonly encountered GU abnormalities on fetal MRI include both upper urinary tract obstruction (UPJ stenosis) and lower urinary tract obstruction such as posterior urethral valves (Fig. 14). More complex

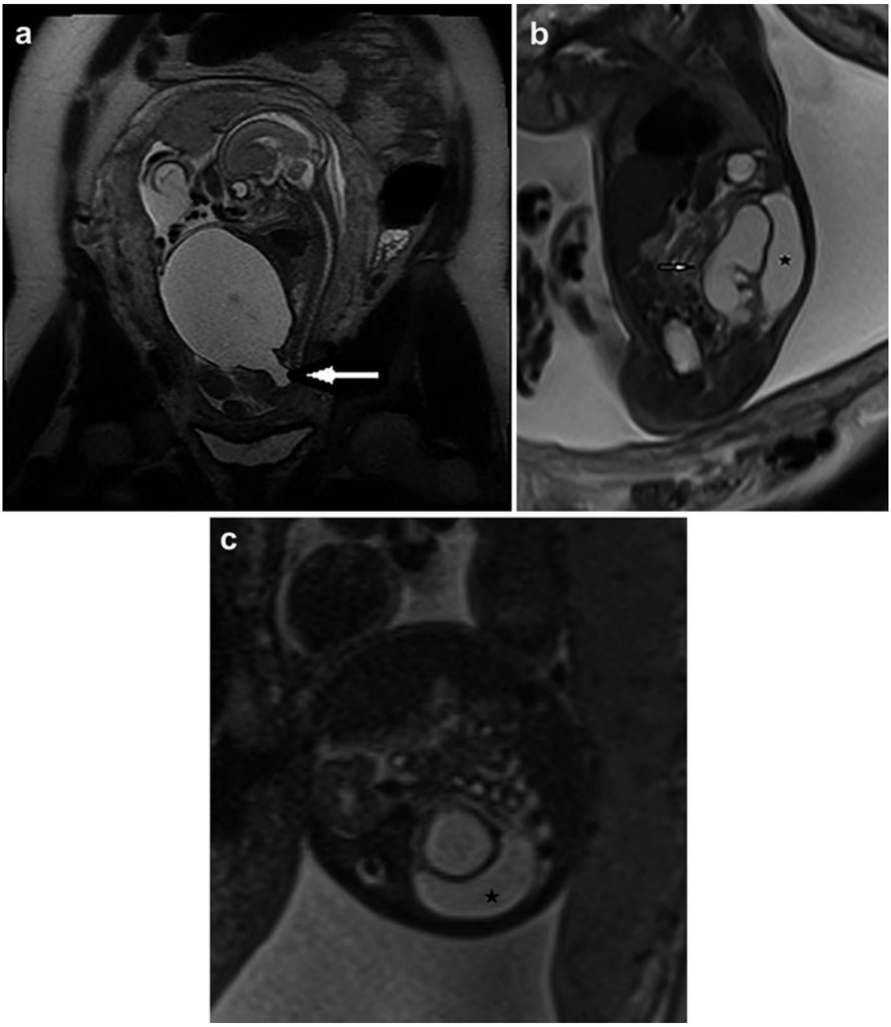

Fig. 14 (**a**) Sagittal T2-weighted fetal MR image of 28-week fetus with dilated bladder and posterior urethra (arrow) in the setting of posterior urethral valves. (**b**) Coronal and (**c**) axial images of a 26-week fetus with left ureteropelvic junction stenosis (arrow) resulting in perforation and retroperitoneal urinoma formation (star)

abnormalities such as cloacal malformations and bladder exstrophy can also be observed with fetal MRI [112].

Megaureter

Megaureter may be primary or secondary to VUR or obstruction. VCUG permits identification of VUR, and diuretic scintigraphy establishes the presence or absence of obstruction. MRU provides excellent anatomic detail, often allowing identification of the site of obstruction [113].

Ureterocele

Ureteroceles may be demonstrated by US, VCUG, IVP, or MRU (Fig. 15). An everting ureterocele may be confused with a bladder diverticulum on VCUG [114]. Ureteroceles may obstruct the urethra during voiding.

Ureteropelvic Junction Obstruction

UPJ obstruction is one of the most common congenital kidney disorders, and most cases are now

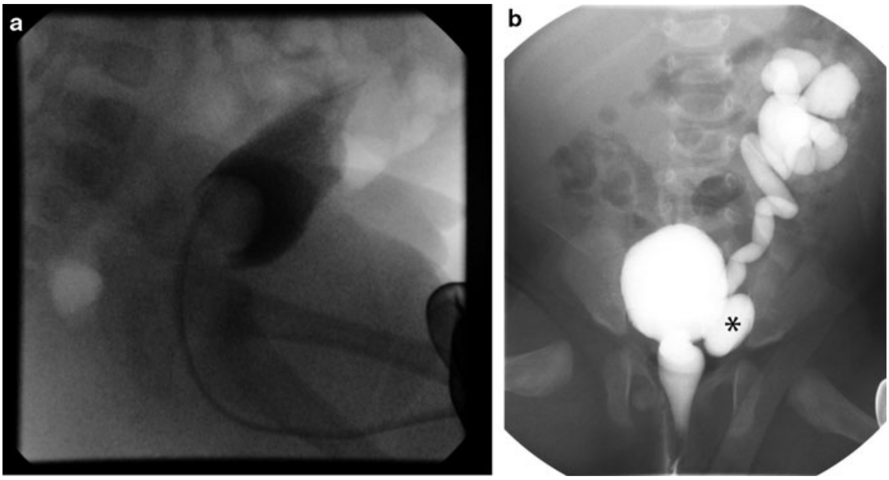

Fig. 15 Ectopic ureterocele with vesicoureteral reflux. (**a**) Voiding cystourethrogram shows rounded filling defect in bladder base from ureterocele. (**b**) Voiding cystourethrogram shows reflux into the lower pole moiety of the left duplex system with eversion of the ureterocele (asterisk). Opacification of the kidney indicates intrarenal reflux

diagnosed by fetal US. Dynamic renal scintigraphy remains the gold standard imaging technique for diagnosing UPJ obstruction (Fig. 16). MRI is an alternative approach that provides functional information and superior anatomic detail without exposure to radiation, albeit with the need for sedation (Fig. 17; [113]).

Abnormal Kidney Number or Location

Unilateral renal aplasia must be distinguished from an ectopic kidney, which can be located anywhere along the course of renal ascent. These ectopic kidneys are often smaller in size. Detection by US is possible, but MRI, IVP, or DMSA is often necessary. IVP may have limited sensitivity if the ectopic kidney has poor renal function.

Horseshoe Kidney and Crossed Fused Ectopia

Horseshoe kidney, with an incidence of 1 of 400 births, is the most common fusion anomaly. Crossed ectopia occurs in an estimated 1 of 1,000–2,000 births. While US can be diagnostic, additional imaging, including IVP, MRI, CT, or DMSA, is often necessary to establish the diagnosis (Figs.18 and 19).

Renal Dysplasia

Renal dysplasia is a histological diagnosis characterized by primitive ducts and cartilage. US evaluation demonstrates increased echogenicity; most dysplastic kidneys are decreased in size. US may detect cysts, which may vary in size and number. The incidence of multicystic dysplastic kidney (MCDK) is estimated at 1 in 2,500 newborn [115]; it is one of the common prenatally detected fetal anomalies. Postnatal US shows cysts of varying size that do not appear to communicate with each other or the collecting system and a small amount of abnormal-appearing renal parenchyma. It may be difficult to differentiate MCDK from severe hydronephrosis [116]. In MCDK, there is typically no communication between cysts, and the larger cysts are not medial (Fig. 20). In hydronephrosis, the calices extend outward from the dilated renal pelvis, and there is functional renal

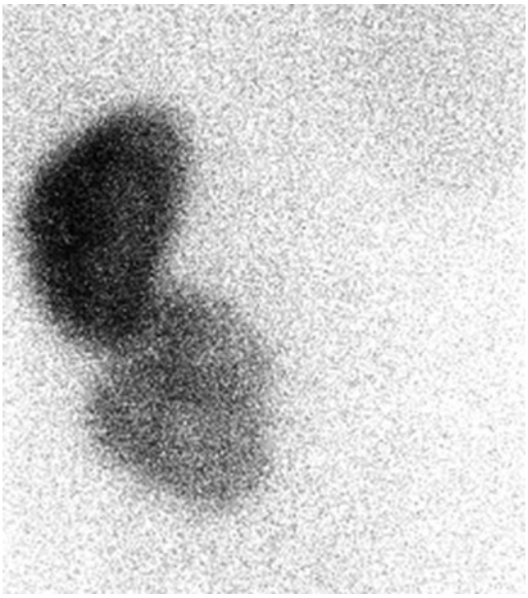

Fig. 18 Crossed fused ectopia. DMSA renal scan anterior image demonstrates a single fused renal moiety on the right

parenchyma surrounding the central cystic structure. If the diagnosis is unclear, a DMSA shows uptake of tracer if hydronephrosis is present, but usually no uptake with MCDK (Fig. 21). Alternatively, MRI can distinguish these two entities.

Duplex Collecting System

A duplex collecting system is a common incidental finding and usually of limited clinical significance unless hydronephrosis is also present. Associated anomalies include ureterocele, VUR, ectopic ureters, renal dysplasia, and UPJ obstruction (Figs. 22 and 23). The upper pole is more likely to be associated with obstruction at the distal ureter, while the lower pole is often associated with VUR or UPJ obstruction. US can usually demonstrate division of the kidney but is not reliable in distinguishing between a bifid ureter and complete ureteral duplication. MRU delineates the anatomy of the ureteral duplication when such information is necessary for planning surgery [117]. MRU is especially useful for characterization of the distal ureter. VCUG may demonstrate VUR or ureterocele.

Ectopic Ureters

Ectopic ureters are three times more common in girls, and approximately 80 % are associated with a duplicated collecting system and ectopic insertion of the upper pole ureter. Greater distance from the

Fig. 19 Horseshoe kidney. CT scan of abdomen shows a horseshoe kidney with a bridge of renal tissue fused across the midline (arrow)

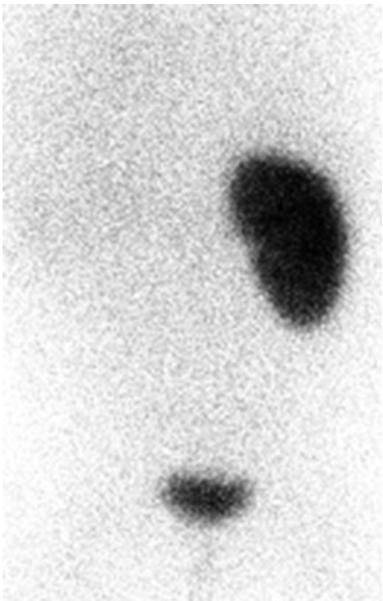

Fig. 21 Left multicystic dysplastic kidney. DMSA renal scan (posterior image) shows no uptake in the left multicystic dysplastic kidney

normal ureter insertion site is associated with more severe ipsilateral renal abnormalities [118]. US can demonstrate duplication, hydronephrosis, megaureter, and abnormal renal parenchyma. MRU often allows detection of the ectopic ureter [113]. VCUG is useful for showing reflux and may indicate the insertion point of the ureter if it is proximal to the external sphincter. DMSA is useful for identifying an ectopic kidney that is the source of an ectopic ureter in a patient with unexplained incontinence [91]. By indicating relative renal function, DMSA may also help with surgical planning.

Bladder Abnormalities

US and VCUG are the standard imaging modalities for patients with a neurogenic bladder (Fig. 24). VCUG readily identifies bladder diverticula, which are easily missed by US. Bladder

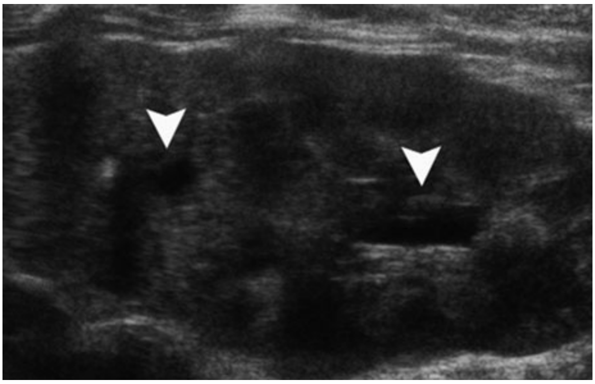

Fig. 22 Duplex system with ectopic ureterocele. Renal US shows mild hydronephrosis (arrowheads) of the upper and lower poles. A band of renal tissue extends across the midpole, indicating a duplex system

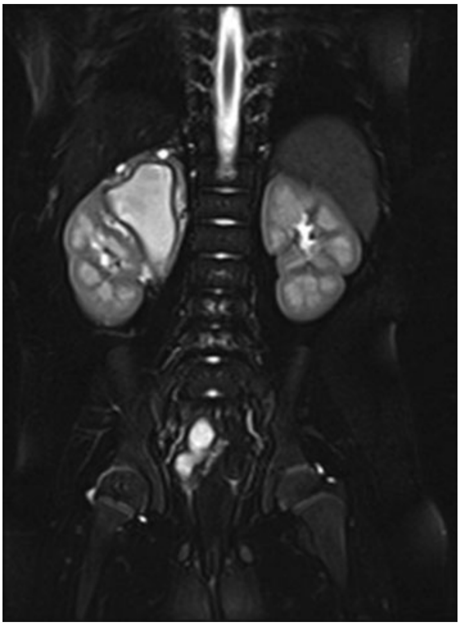

Fig. 23 Duplex system with ectopic ureterocele. MRU shows hydronephrosis of the right upper pole

wall thickening, which is consistent with high bladder pressures, can be quantified by US.

Urethral Abnormalities

VCUG is the definitive test for diagnosing posterior urethral valves (Fig. 25). The prostatic urethra is dilated, the membranous urethra is stenotic, and the distal urethra appears normal. Secondary VUR, hydronephrosis, and bladder abnormalities are often present (Fig. 26). Other urethral abnormalities (anterior urethral valves, urethral duplication, Cowper's duct cyst, urethral diverticulum, megalourethra) are also visualized well via VCUG.

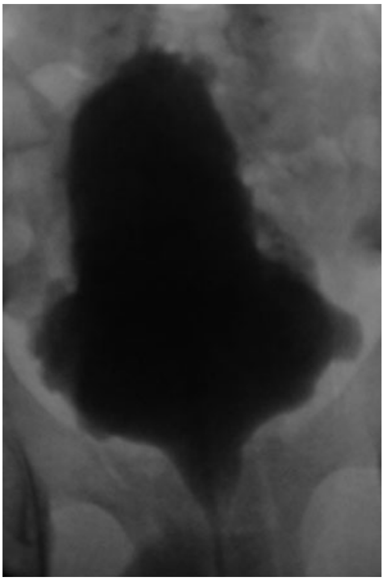

Fig. 24 Neurogenic bladder in a 16-year-old with a spinal cord injury. Voiding cystourethrogram shows pear-shaped bladder with trabeculations

Vesicoureteral Reflux

VCUG is the gold standard for diagnosing VUR, with reflux grades based on the International Reflux Study in Children (Fig. 27) [51]. In clinical situations where the purpose of the study is solely to assess the patient for VUR, RNC and CEVUS are appropriate substitutes for VCUG because of decreased or no radiation burden, respectively.

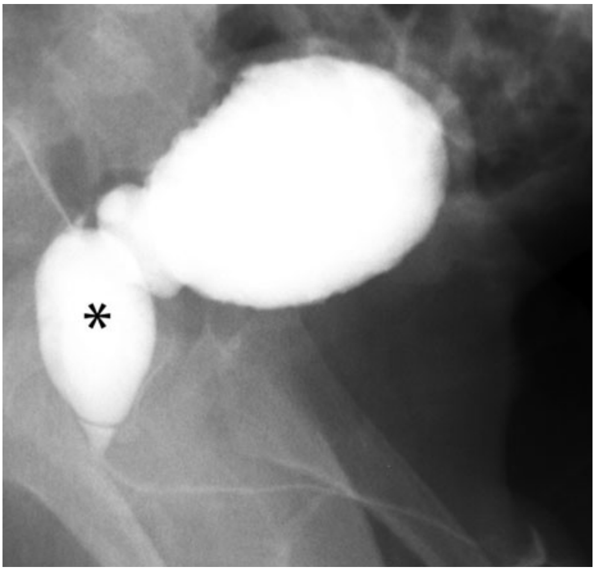

Fig. 25 Voiding cystourethrogram shows dilatation of the posterior urethra (asterisk) in a boy with posterior urethral valves

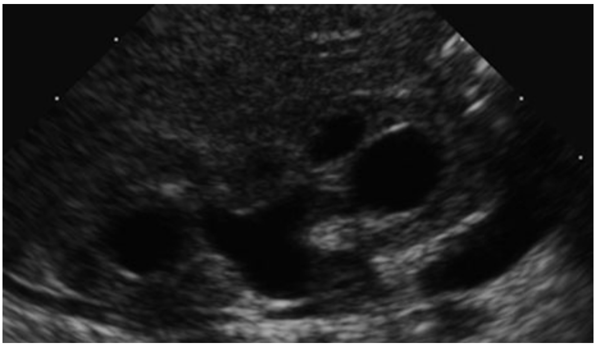

Fig. 26 Renal US shows dilatation of the right renal pelvis, calices, and ureter in a boy with posterior urethral valves

Examples include follow-up studies in children with previously diagnosed VUR, and potentially for the initial evaluation of girls with urinary tract infections (where there are no risks of posterior urethral valves). Renal US lacks adequate sensitivity and specificity for diagnosing VUR [119, 120], although high-grade VUR is more likely if hydronephrosis is present [121].

Hereditary Disorders

Cystic Kidney Diseases

In autosomal recessive polycystic kidney disease (ARPKD), intravenous pyelogram (IVP) shows enlarged kidneys with a delayed nephrogram [122]. Radial streaks due to contrast in the dilated collecting ducts are usually present in infancy but may not be visible in older children. Because of concerns regarding IV contrast, a renal US is now the usual initial diagnostic test (Fig. 28). US shows enlarged kidneys with increased echogenicity and poor corticomedullary differentiation; a hypoechoic rim is often visible [123]. Older children have increased medullary echogenicity, which may resemble nephrocalcinosis [124]. Multiple small cysts may or may not be visible by US [124, 125]. Macrocysts are sometimes visible in older children [125].

In autosomal dominant polycystic kidney disease (ADPKD), US, CT, and MRI are useful for detecting macroscopic cysts and associated complications (Figs. 29 and 30) [126]. The number and size of cysts in children increases with age, and those patients with more cysts have increased

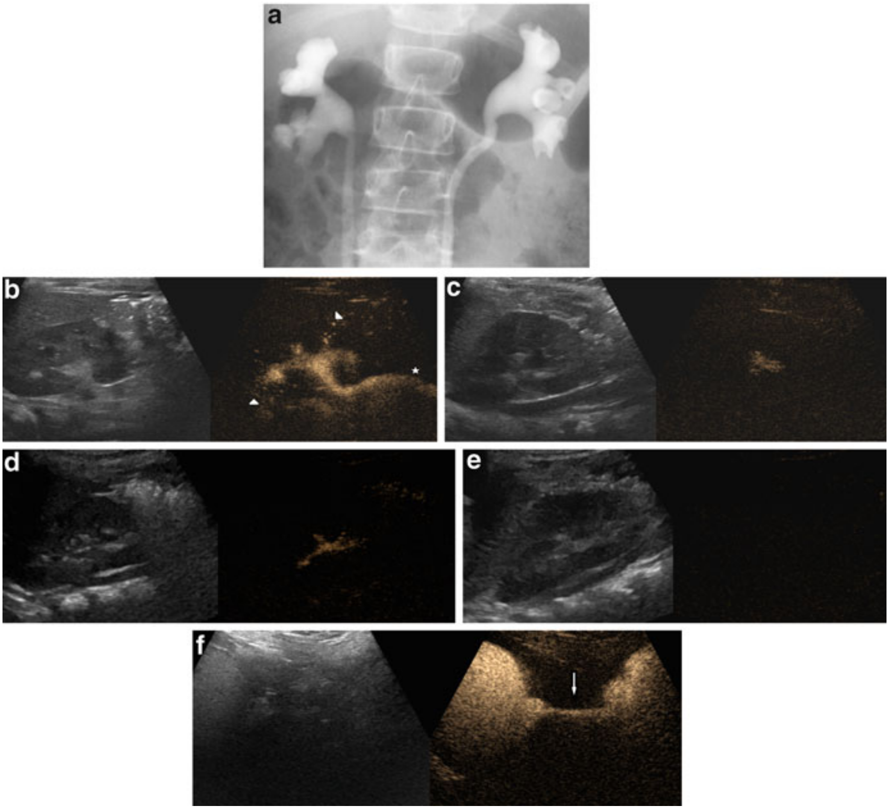

Fig. 27 Vesicoureteral reflux. (**a**) Voiding cystourethrogram shows bilateral grade 4 vesicoureteral reflux. 6-month follow-up longitudinal CEVUS images of the right (**b**) and left (**c**) kidneys show improved reflux on the left with persistent grade 4 reflux on the right, with intrarenal reflux (arrowheads). 18-month follow-up CEVUS images on the right (**d**) and left (**e**) kidneys with grade 2 reflux on the right and resolved reflux on the left. kidney size [127, 128]. ADPKD rarely causes renal failure in childhood [37, 129]. In adults, kidney size measured by MRI predicts decline in renal function [126]. Increased renal echogenicity may be seen in some children [125]. Children occasionally have marked disease asymmetry, which can create diagnostic confusion [130]. Both ARPKD and ADPKD can have associated liver abnormalities [131]. Extrarenal complications of ADPKD include liver cyst infection/

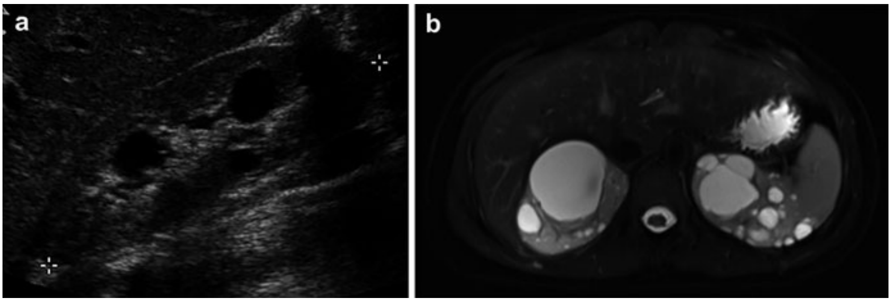

Fig. 29 Autosomal dominant polycystic kidney disease. (**a**) Renal US, longitudinal image, bilateral renal cysts of varying sizes in a 15-year-old. (**b**) MRI, axial fat-saturated T2 weighted image with multiple bilateral T2 hyperintense renal cysts

hemorrhage, intracranial aneurysms, and valvular heart disease [126].

US in nephronophthisis shows hyperechoic kidneys with loss of corticomedullary differentiation and that are of normal or slightly decreased size. Medullary cysts are a hallmark of the disease, although they are not always detected by US [132]. CT and MRI are a more sensitive methods for identifying medullary cysts [133]. The diagnosis of medullary sponge kidney is classically based on characteristic IVP changes showing stagnation of contrast in one or more renal papillae due to dilation of the collecting ducts. The resultant image has been described as a “pyramidal blush.” CT is an alternative approach given the decline in IVPs and may expose patients to less radiation [134, 135]. In medullary cystic disease, the kidneys are usually normal or small, and US or CT may show a few medullary cysts [136].

Tuberous Sclerosis

Angiomyolipomas are the most common renal lesion in tuberous sclerosis (TS) and are readily seen by CT or US (Figs. 31 and 32). Children with disruption of the contiguous *PKD1* and *TSC2* genes usually have severe cystic disease and are at high risk for hypertension and early kidney failure [137]. Renal malignancies, including renal cell carcinoma and malignant angiomyolipomas, are a serious concern in TS, and both are seen in children, sometimes in early childhood [138, 139]. All children with TS should have a renal US at diagnosis and follow-up renal US testing every 1–3 years, with frequency dictated by the specific clinical situation [140]. Patients with extensive or rapidly changing lesions require more frequent follow-up. Those with more severe kidney disease may require CT or MRI to screen for malignant changes.

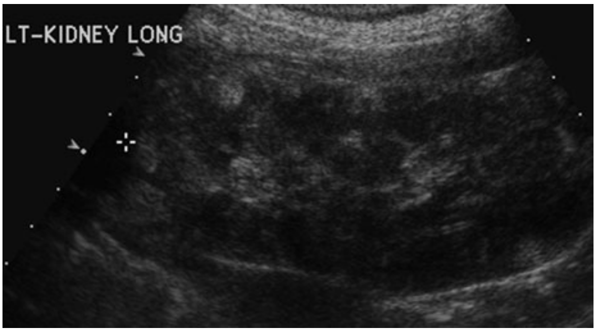

Fig. 31 Angiomyolipomas in tuberous sclerosis. Renal US, longitudinal image, demonstrates multiple small echogenic lesions throughout the kidney. The increased echogenicity is related to intralesional macroscopic lipid

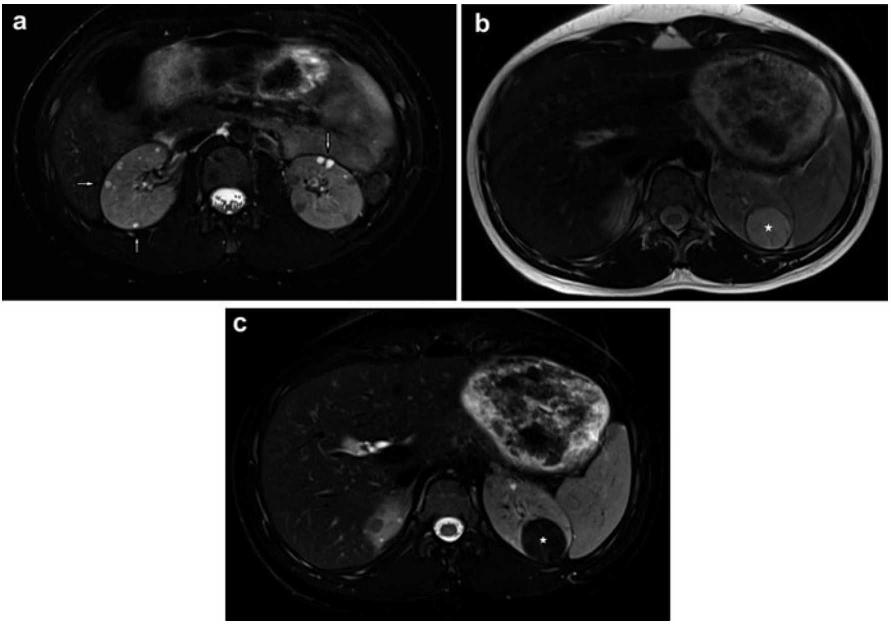

Fig. 32 Tuberous sclerosis on MRI. (**a**) Axial T2 fat saturated T2 weighted image with multiple small bilateral T2 hyperintense cysts (arrows). Axial T2 weighted images without (**b**) and with (**c**) fat suppression demonstrated an angiomyolipoma in the upper pole of the left kidney (star)

Differentiating angiomyolipomas from malignancy requires careful comparison of sequential images.

Infections of the Urinary Tract

Clinical and laboratory criteria do not reliably differentiate pyelonephritis from cystitis [141–143]. DMSA is the gold standard for diagnosing acute pyelonephritis, although MRI and CT provide similar sensitivity [143]. US may detect loss of corticomedullary differentiation and renal enlargement, but lacks adequate sensitivity and specificity when compared to CT (Fig. 33) or DMSA [144–147]. The decreased uptake using DMSA with pyelonephritis may be focal, multifocal, or diffuse. Acute pyelonephritis must be differentiated from renal scarring, which is associated with sharper borders and loss of cortical volume. DMSA may allow diagnosis of pyelonephritis in children who have received antibiotics prior to urine culture or who have a negative culture despite clinical and laboratory evidence suggesting pyelonephritis [148].

DMSA is the current standard modality for diagnosing renal scarring (Fig. 34), with increased

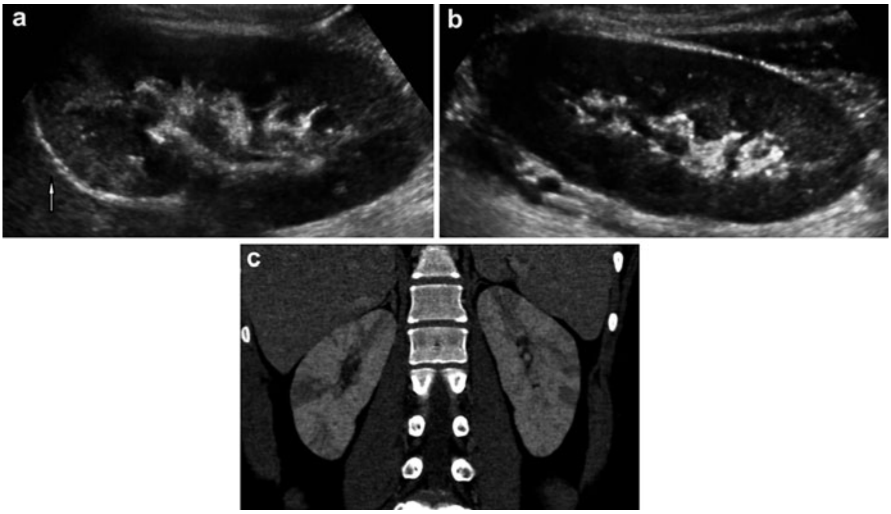

Fig. 33 Acute pyelonephritis. Prone longitudinal images of the left (**a**) and right (**b**) kidneys of a 12-year-old female demonstrate a wedge-shaped region of increased echogenicity in the upper pole of the left kidney. (**c**) Coronal post-contrast CT image of a 10-year-old female with bilateral nephrographic striations, characteristic of acute pyelonephritis

sensitivity when compared to US. Scars appear as photopenic areas with volume loss. DMSA should be deferred at least 6 months after an acute infection to differentiate a transient lesion due to infection from a scar [90, 149, 150]. MRI has the potential to differentiate acute pyelonephritis from renal scarring, which may avoid the need for radiation exposure and obviating the need for two diagnostic tests [151].

Renal Failure

US is the initial imaging modality when a patient presents with unexplained renal failure. Imaging must include assessment of renal size, echogenicity, morphology, cystic disease, and hydronephrosis [3]. US generally allows differentiation of chronic kidney disease (small, echogenic kidneys with a thin cortex) from acute kidney injury. In the pediatric population, the most common cause of end-stage kidney disease is congenital anomalies of the kidneys and urinary tract (CAKUT). This term encompasses abnormalities of the urinary tract (upper and lower tract obstruction as well as VUR), abnormalities related to renal ectopia, and disorders of nephron development (renal cystic disease and dysplasia) [3]. The kidneys may be large if chronic kidney disease is secondary to polycystic kidney disease. US readily detects hydronephrosis, which suggests that renal failure is due to an obstructive etiology. Hydronephrosis may also be secondary to VUR, papillary necrosis, or high urine output; such hydronephrosis is rarely severe.

Renal parenchymal disease is often associated with increased echogenicity, although a normal US examination does not exclude this possibility. The kidneys generally have a normal appearance in prerenal azotemia. The kidneys may be normal or have increased echogenicity in acute tubular necrosis. Echogenic kidneys, which may be moderately enlarged, are often seen in glomerular disease (Fig. 35) [152, 153]. The kidneys are enlarged and very echogenic in HIV nephropathy [154]. The US findings in renal parenchymal disease are rarely specific.

Renal Transplant

US is the primary imaging modality for evaluation of the renal transplant [32, 155, 156]. US can identify posttransplant complications, including

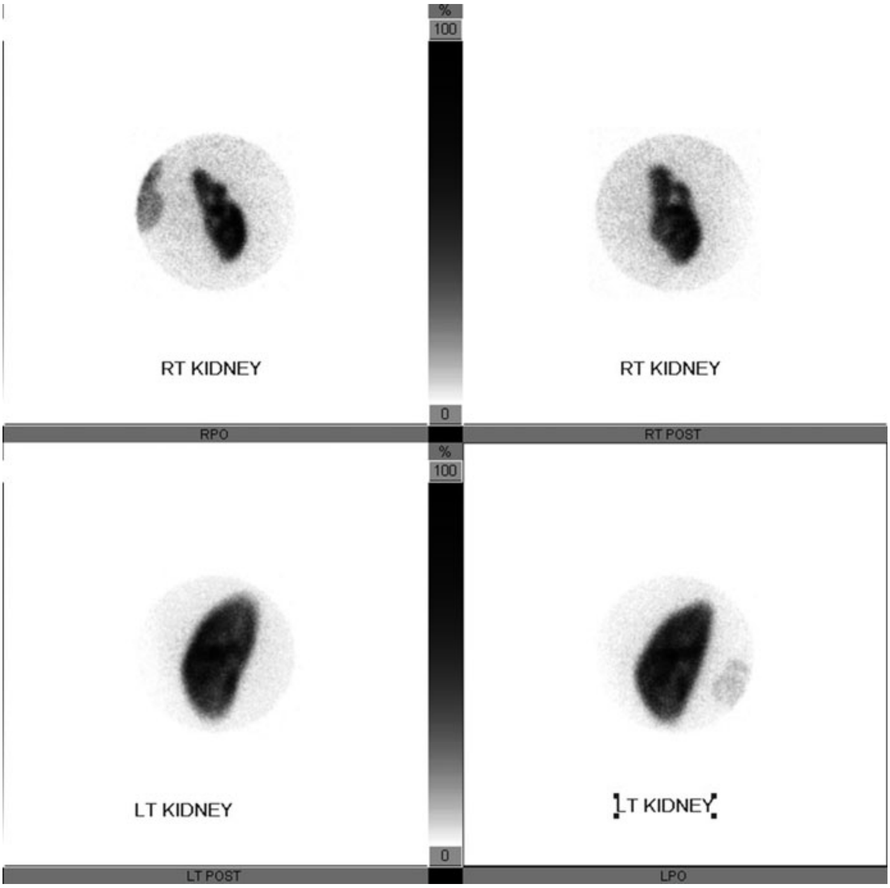

Fig. 34 Renal scarring in a 10-year-old with vesicoureteral reflux. DMSA renal scan shows a small right kidney with diffuse renal scarring. Uptake in the right kidney is 20%

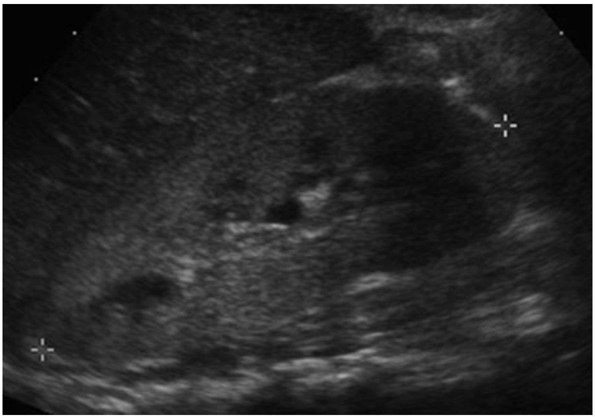
Fig. 35 Acute glomerulonephritis in a 3-year-old. Renal US shows large echogenic right kidney



abnormal fluid collections (e.g., lymphoceles, urinomas; Fig. 36), obstruction, and mass lesions. Doppler US can detect vascular disease after kidney transplant (renal artery thrombosis, renal artery stenosis, renal vein thrombosis, arteriovenous fistula) [155, 156]. Patients with acute graft rejection may have many US abnormalities (increased renal size and echogenicity, decreased

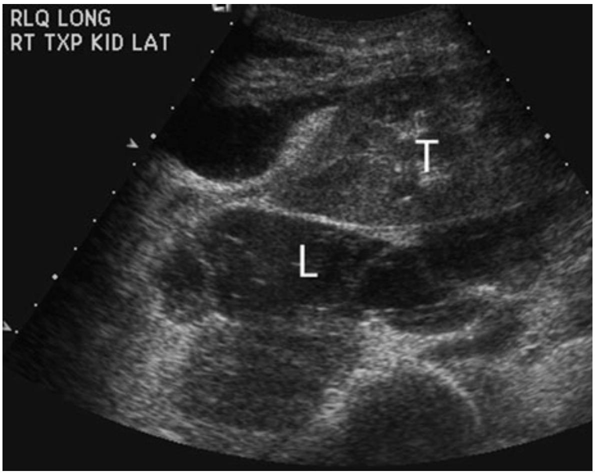


Fig. 36 Lymphocele in a 15-year-old with a renal transplant. Renal US shows a complex, loculated fluid mass adjacent (L) to the transplanted kidney (T)

or absent central sinus echoes); however, US does not have adequate sensitivity or specificity for diagnosis of rejection (for which kidney biopsy remains the gold standard for the diagnosis). Acute rejection, vascular thrombosis, and acute tubular necrosis (ATN) are the most common complications in the immediate postoperative period. Long-term complications include arterial stenosis, ureteral stenosis, chronic rejection, and posttransplant lymphoproliferative disorder [37, 156].

Radionuclide imaging (^{99m}Tc-DTPA or ^{99m}Tc-MAG$_3$) is useful when US does not provide an explanation for graft dysfunction. Absence of flow to the kidney occurs with arterial or venous obstruction or with hyperacute rejection. In contrast, a graft with ATN has normal renal perfusion, but delayed or no excretion. Radionuclide imaging is also useful for demonstrating urinary obstruction or a perinephric fluid collection that is due to a urine leak [157, 158].

Urolithiasis and Nephrocalcinosis

Urolithiasis

US is a sensitive test for detecting calculi in the kidney and the proximal and distal ureter. US does not easily detect stones in the middle portion of the ureter, although hydronephrosis due to obstruction may suggest the diagnosis. Acoustic shadowing is a useful finding but may not be present with smaller calculi. Twinkle artifact, likely secondary to the US beam interacting with stone, can also help identify calculi [37, 159]. US is less sensitive than CT in detecting calculi in symptomatic children (Fig. 37) [160]. CT is also superior to US for identification of bladder stones, especially in patients with bladder augmentations.

Nephrocalcinosis

Nephrocalcinosis is typically detected by US (Fig. 38), although it may be also seen via CT. Plain X-ray only detects nephrocalcinosis in severe cases [161]. Primary hyperoxaluria and cortical necrosis are some of the causes of cortical nephrocalcinosis, while many entities may cause medullary nephrocalcinosis [162].

Trauma to the Urinary Tract

CT with contrast is the primary modality for evaluating a patient with suspected trauma to the kidney (Fig. 39) [163]. CT angiography permits detailed evaluation of the renal artery and vein. US is an alternative imaging modality that may identify large lacerations, hematomas, and urinomas; US with Doppler readily identifies significant injuries of the renal artery or vein. US suggests bladder laceration when there is a large

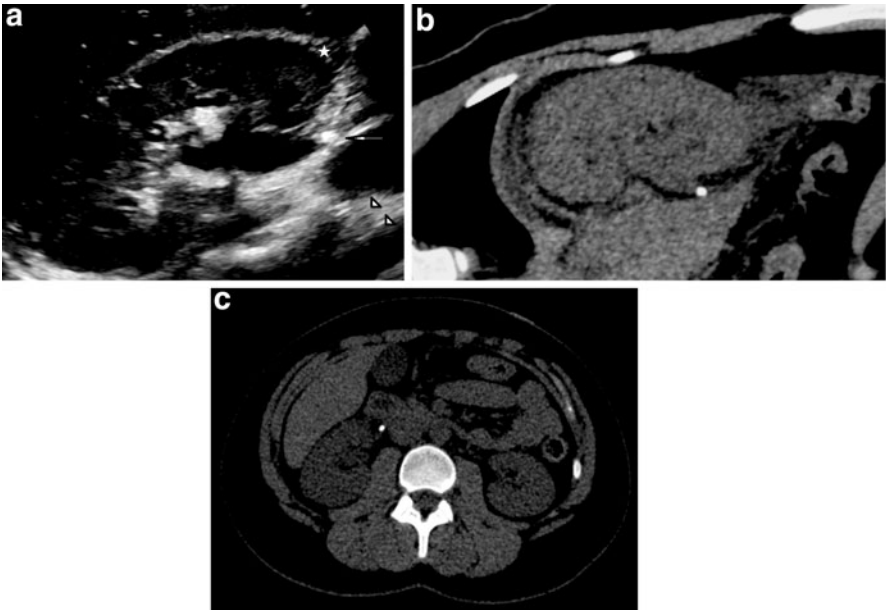

Fig. 37 Nephrolithiasis. (**a**) Longitudinal image of the right kidney with echogenic calculus at the right ureteropelvic junction (arrow) with faint posterior shadowing (arrowheads). Note perinephric edema adjacent to the lower pole (star). Matched plane (**b**) and axial (**c**) non-contrast CT images from same patient

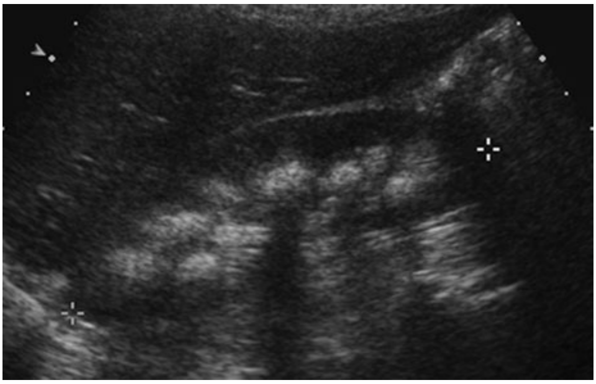

Fig. 38 Medullary nephrocalcinosis in a 12-year-old with renal tubular acidosis. Renal US, longitudinal image, shows echogenic renal pyramids

amount of fluid in the cul-de-sac. When indicated, VCUG can potentially identify the site of bladder leak and detect urethral injury.

Renal and Urinary Tract Tumors

Role of Imaging

US is especially suited for initial evaluation, while CT or MRI is necessary for defining tumor extent and the presence of metastases. CT without contrast allows for identification of tumor calcifications; contrast allows for better differentiation of tumor from normal tissue. US is sensitive for the detection of bladder tumors in children [164].

Imaging of Specific Renal Tumors

Wilms' Tumor

US and CT are complementary in the evaluation and follow-up of Wilms tumor (Figs. 40 and 41) [165, 166]. US with Doppler may provide superior imaging of tumor in the inferior vena cava in some

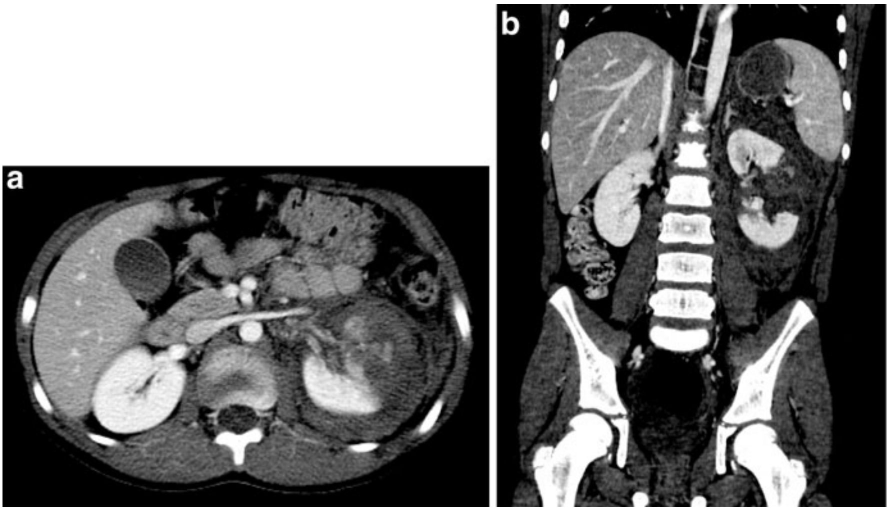

Fig. 39 Motor vehicle collision resulting in extensive left renal laceration with a large perinephric hematoma. A: Axial CT. B: Coronal CT

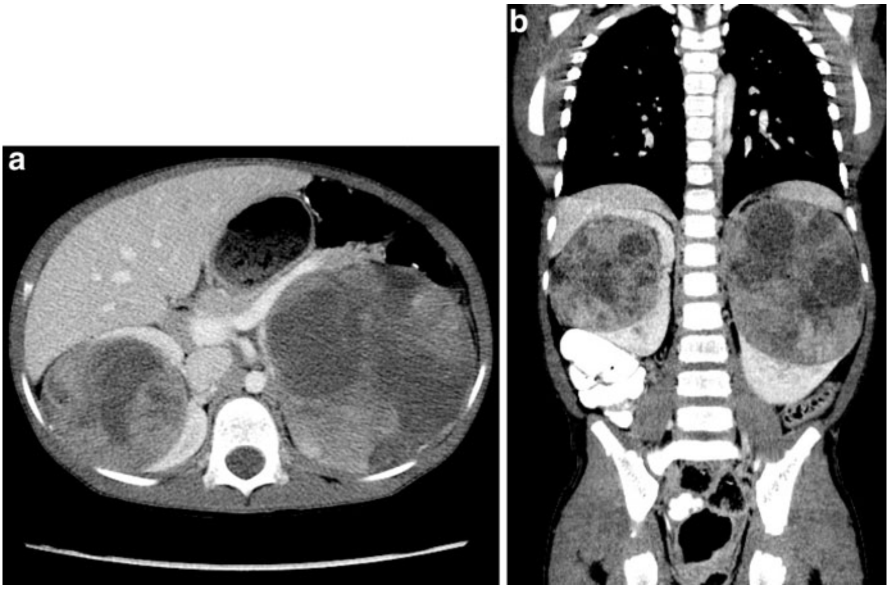

Fig. 40 Bilateral Wilms tumor in a 5-year-old with a palpable abdominal mass. (**a**) Axial CT. (**b**) Coronal CT

patients. Radiologic staging of Wilms tumor includes chest X-ray, US of the abdomen and pelvis, and CT of the chest, abdomen, and pelvis. MRI is also an effective modality for evaluation of Wilms tumor [165, 166]. US is a sensitive approach for screening patients for tumor recurrence, although CT or MRI is necessary to identify nephrogenic rests [165]. US is the preferred modality for Wilms tumor screening, which is necessary in children with syndromes that significantly increase the risk of Wilms tumor (e.g., hemihypertrophy, Denys-Drash syndrome, Beckwith-Wiedemann syndrome) [167]. Screening frequency and duration varies depending on the syndrome.

Lymphoma

Children with lymphoma may have renal involvement. By US, renal lymphoma has decreased echogenicity [168]. CT may demonstrate “contrast inversion” of the lesions in renal lymphoma: increased density compared to normal parenchyma without contrast and decreased density with contrast [168].

Vascular Disease and Hypertension

Renal Artery Stenosis

Doppler US may detect renal artery stenosis in children [169], but sensitivity is limited [170]. US may demonstrate a small affected kidney if the stenosis is severe and long-standing. CT and MRI angiography provide excellent visualization of the extraparenchymal renal artery (Fig. 42), the most

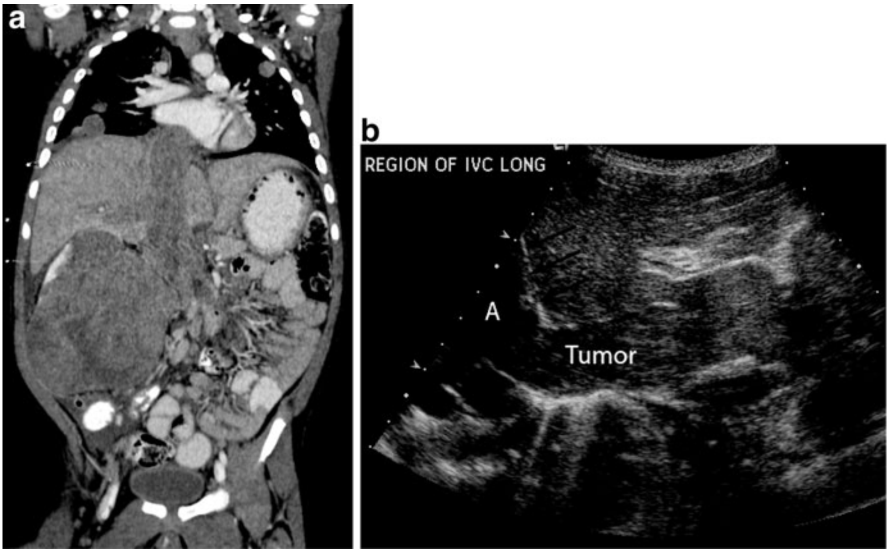

Fig. 41 Wilms tumor in a 2-year-old. (**a**) Coronal CT image shows a large right renal mass, pulmonary nodules, and tumor extension into the IVC to the diaphragm. (**b**) Longitudinal US image with tumor filling the dilated IVC extending to the diaphragm (arrows) and entering the right atrium (**a**)

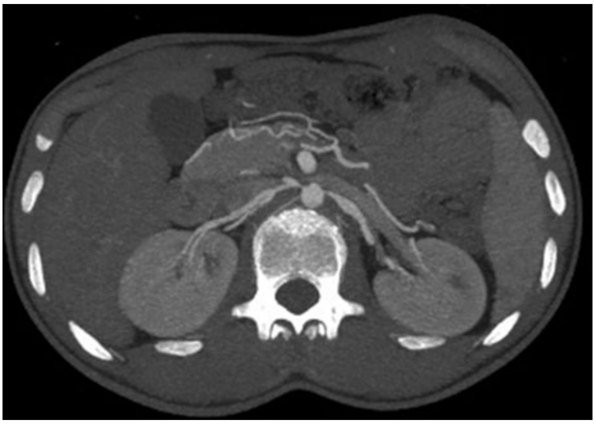
Fig. 42 Renal artery stenosis in a 13-year-old with neurofibromatosis and hypertension. Axial maximal intensity CT image shows narrowing of both renal arteries near their origins from the aorta



common site of disease, but do not visualize distal branch vessel lesions [171]. When clinical suspicion is high, conventional angiography remains necessary to evaluate children with suspected hypertension due to renal artery disease [170].

Renal Vein Thrombosis

US is utilized to diagnose renal vein thrombosis. The appearance on US varies depending on the timing of imaging. Within the first few days of clot formation, imaging may demonstrate pathognomonic echogenic streaks due to clot in interlobular and interlobar veins [172]. Renal enlargement occurs during the first week and is associated with an echogenic cortex and less echogenic medullary pyramids. Beyond the first week, there is a loss of corticomedullary differentiation, and echogenic streaks are no longer visible. An additional later finding is calcification of thrombi within large or small renal veins [173]. Long-term imaging outcomes vary from a normal-appearing kidney to a small, echogenic kidney with little or no function [173]. In perinatal renal vein thrombosis, renal length is negatively correlated with outcome [174].

US may directly demonstrate clots in the renal vein and inferior vena cava. Doppler US may show absent renal venous flow and pulsatility [172, 173]. The arterial RI is frequently elevated. Clot retraction and formation of collaterals after a few days may create diagnostic confusion due to a return of some venous flow and a decrease in arterial RI. In neonates, adrenal hemorrhage, which is readily seen by US, frequently accompanies renal vein thrombosis and assists in confirming the diagnosis [175]. This association is more common on the left due to the common drainage of the renal vein and adrenal vein.

Pheochromocytoma

Pheochromocytoma may be strongly suspected based on clinical and laboratory evaluation, but imaging is necessary to confirm the diagnosis and allow for staging and resection, which is usually curative. US may identify a pheochromocytoma in or near the adrenal gland, but US lacks the sensitivity of CT or MRI, especially for small lesions or tumors in other locations (Fig. 43). Hypertensive crisis may occur if ionic contrast is utilized, but nonionic contrast appears safe at the doses used for CT [176]. Chest CT or MRI is indicated if an abdominal lesion is not detected or for staging of malignant disease. Pheochromocytomas enhance on contrast CT, although non-enhancing foci of necrosis and hemorrhage may be present. MIBG scintigraphy, a complementary imaging modality, may be appropriate as an initial test, to confirm the diagnosis in equivocal cases or to search for disease when the CT or MRI is negative (Fig. 44) [88, 177]. Positron emission tomography (PET) scan is a potential

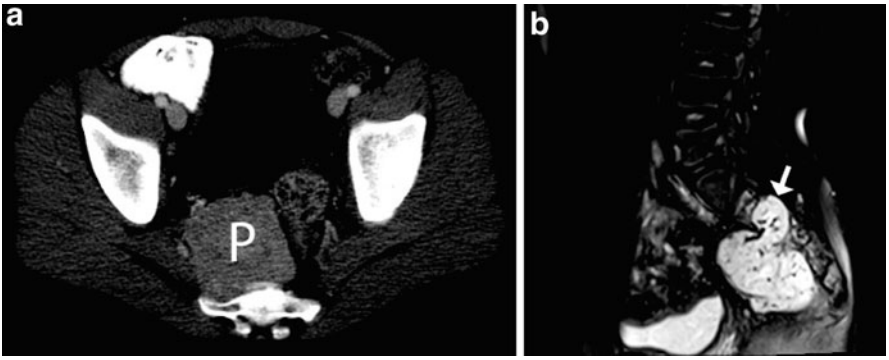


Fig. 43 Pheochromocytoma in a 14-year-old. (**a**) Axial CT image shows a right pelvic mass (P). (**b**) Sagittal T2-weighted MR image shows a right pelvic mass extending into the adjacent neural foramen (arrow)

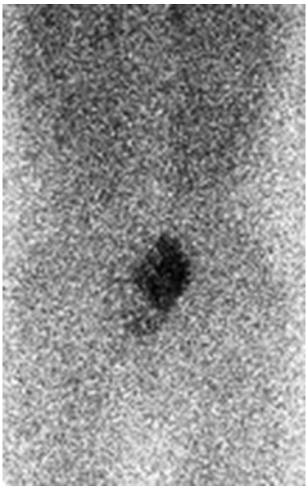

Fig. 44 Pheochromocytoma. Posterior ^{123}I-MIBG image shows uptake into the pelvic tumor

alternative if all other studies are negative and clinical suspicion remains high [178, 179].

Abstract

This chapter reviews technical aspects and different methods of obtaining kidney biopsy material and allocation of the biopsy specimens. We describe the types of microscopy used to analyze the tissue, including light microscopy with special stains, immunofluorescence microscopy, including salvage techniques from paraffin tissue, and electron microscopy. We describe normal morphology and common, classic morphologic patterns of injury. We also describe selected specific patterns of injury, including mesangial versus endocapillary hypercellularity, membranoproliferative pattern, exudative pattern, crescents, segmental sclerosis, thrombosis, acute tubular injury, interstitial fibrosis/tubular atrophy, and acute interstitial nephritis. Lastly, prognostic implications of biopsy findings and new methods on the horizon are briefly discussed.

Biopsy · Biopsy complications · Tissue allotment · Light microscopy · Immunofluorescence · Electron microscopy · Paraffin immunofluorescence · Mesangial hypercellularity · Endocapillary hypercellularity · Crescents

Introduction

This chapter reviews the methods of obtaining the biopsy material and analyzing the tissue and considerations in allocation of biopsy tissue. Normal morphology and examples of classic morphologic patterns of injury are described. Last, experimental techniques that may provide important pathogenic, prognostic, or diagnostic information are discussed.

Obtaining Tissue

General Considerations

Although some renal diseases show diagnostic features by light microscopy (LM), special studies add to the sensitivity of the study. For the renal biopsy to be most useful, it must be evaluated appropriately by an experienced renal pathologist. Biopsies must be examined by specialized LM, immunofluorescence (IF), and electron microscopy (EM) techniques for the most accurate diagnosis [42, 73]. If the nephrologist's hospital does not provide these services, arrangements must be made to send tissue in appropriate fixatives (see below) to a reference laboratory with these capabilities. If such services cannot be provided, it is doubtful whether the institution should be undertaking renal biopsies. Knowledgeable interpretation of light, immunofluorescence, and electron microscopic findings correlated with clinical and laboratory data by a trained renal pathologist in consultation with the treating nephrologist is required for the correct diagnosis [12, 32].

Percutaneous Renal Biopsy

Percutaneous renal biopsy is the most common method for obtaining tissue for the kidney. The technique, first reported in 1951 by Iversen and Brun, historically allowed adequate tissue in more than 95% of biopsies [31, 74]. Blood pressure must be controlled as there is a ten-fold increased risk of complications with blood pressure greater than 140/90 mmHg [42]. Conditions with increased risk of bleeding (e.g., thrombocytopenia, uremia, abnormal INR, bleeding disorders, anticoagulant therapy) should be corrected prior to biopsy. Contraindications to percutaneous biopsy include abnormal renal vascular supply, inability to accurately image the kidney, and uncontrolled hypertension [5, 29]. In the era of ultrasound guidance and automated biopsy instruments, a solitary, ectopic, or horseshoe kidney may be biopsied safely in selected patients [5, 23, 29]. Relative contraindications include obesity, uncooperative patients, hydronephrosis, ascites, pregnancy, and small scarred kidneys, all associated with greater risk for complications. Open or modified open biopsy is preferable if the biopsy information is crucial in these conditions. Percutaneous biopsy is also contraindicated if the kidney has tumors, large cysts, abscesses, or pyelonephritis because the needle track may facilitate spread of malignant cells or infection. Open biopsy allows selection of specific areas for biopsy in these situations.

Food and drink should have been withheld for at least 6 h before biopsy, and the child should be lightly sedated. The patient is prone usually with a sandbag or rolled sheet beneath the abdomen for correct positioning, with surgical sterile preparation of the flank and the lower pole of the kidney located by computed tomography (CT) or ultrasound, the last being the most commonly used method. The left is preferred because in most cases, no other organ hinders access. However, if bowel or splenomegaly blocks access, the other kidney should be visualized, or the procedure halted. Local anesthetic is infiltrated first in the skin and then in deeper tissues, taking care not to enter the kidney, and the needle or trocar introduced. Ultrasound shows the needle as it is advanced towards the kidney in real time. The operator will feel the change in resistance as the needle reaches the kidney and then ultrasound will reveal the angle of approach and needle location relative to the capsule at the lower pole [13, 15, 16, 26, 44]. If the needle has entered the kidney, it should be retracted, slightly redirected, and localized with ultrasound for correct placement (Fig. 1). The speed of automated biopsy needles minimizes the need for the patient to hold respirations, required with conventional needles. Computed tomography (CT)-guided biopsies differ in that the kidney to skin distance is determined and a trocar is placed. CT is repeated to determine the angle of approach and that the trocar is at the kidney capsule.

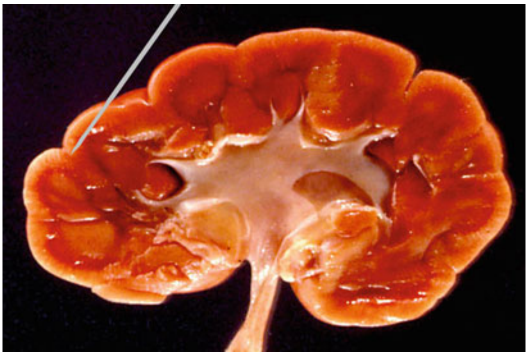

Fig. 1 Cross section of a kidney from a four-year-old boy. Schematic needle enters at the lower pole and captures only cortex because of the correct placement and angle

Needle gauge determines the quality, volume, and glomerular number obtained (Fig. 2). The internal diameter of the 18 g needle (300 μm) is slightly larger than the diameter of a normal glomerulus (200–250 μm, in patients 2 years and older) [17, 67]. As a result, an 18 g needle results in about 50% lost, fragmented, or floating glomeruli (Fig. 3) [71]. It is therefore highly recommended that a 16 g needle is always used in children beginning at age two and the 18 g needle reserved for infants and young toddlers.

The biopsy needle ideally advances through the cortex with little medulla (Fig. 1). Inclusion of the corticomedullary junction in pediatric biopsies is useful because the segmental lesions of focal segmental glomerulosclerosis (FSGS) start in this location in the earliest stages of disease. Two or three passes are planned but the number of passes depends on the patient's status during the procedure and the tissue obtained with each pass. A postbiopsy ultrasound can be done, and, in the absence of active extravasation, the patient is very unlikely to develop a late major hemorrhagic complication. Pressure is applied to the site and a bandage placed. The patient should lay supine in bed for 6 h and may be discharged usually after

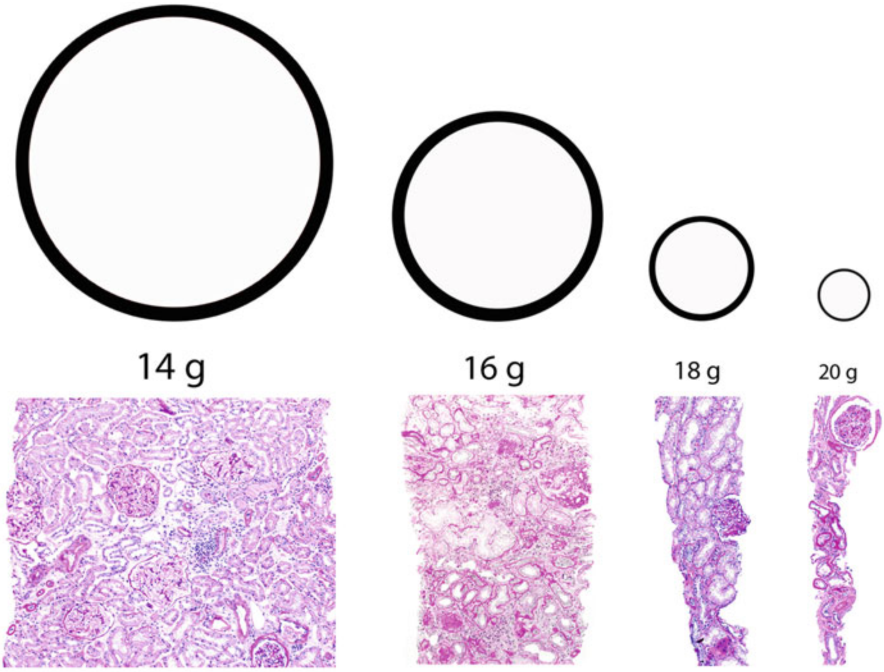

Fig. 2 Needle gauge and tissue width. The typical internal diameter of the various gauges of biopsy needles are shown at the top. Sections of renal biopsy tissue obtained from each gauge are shown below (original magnification 200×). The mean diameter of tissue sections obtained with each needle gauge is shown beneath ($n = 25$ personal communication, PDW). For reference, the diameter of a typical glomerulus from children 2 years and older is 200–250 μm

6–12 h. Vital signs, complete blood counts, and urinalysis for blood are monitored till discharge. The patient is instructed to rest at home for at least the next 24 h. Those with post biopsy perinephric hematomas, postbiopsy gross hematuria, or very young children can be observed overnight so that hemostasis is assured [62, 63, 69].

Complications are recognized within 8 h of the biopsy in most cases [3, 70, 72]. Microscopic hematuria is the most common finding (almost 100%) followed by a hematoma at the biopsy site (>90% in controlled studies) [51], pain at the biopsy site (4%) [50], and macroscopic hematuria 4%. Symptomatic arteriovenous fistula formation occurs in <5%. However, when using renal ultrasound and Doppler mapping, an arteriovenous fistula was found in 14% of patients 24 h after biopsy [66]. None in their series required intervention and all self-closed over the next one to 5 months. Very rarely, arteriovenous fistulae are symptomatic with falling renal function, significant macroscopic hematuria, etc., and these generally require intervention [18, 53]. In systematic reviews, major complications following biopsy occurred in <2% of patients overall including bleeding requiring transfusion (6%), radiologic intervention (0.3%), or nephrectomy (0.01%) [1, 4, 7, 8, 35]. Death due to biopsy occurred in up to 0.06% of all biopsies with 0.03% in outpatient biopsies [50]. Rarely, development of bladder clots can be obstructive and require Foley catheterization and irrigation. Other complications have been reported, including retroperitoneal hemorrhage, inadvertent puncture of other viscera or major renal vessels, sepsis, renal infection, and seeding of cancer. The safety of the biopsy depends upon the correct angle of approach, accurate localization to the lower pole, and placement of the needle on, not through, the capsule. Though perhaps counter-intuitive, the needle gauge plays little or no role in the complication rate in the hands of a trained operator [11, 43]. Over the last decade, as the primary operator has changed from the nephrologist to radiologists in some areas [36], there has

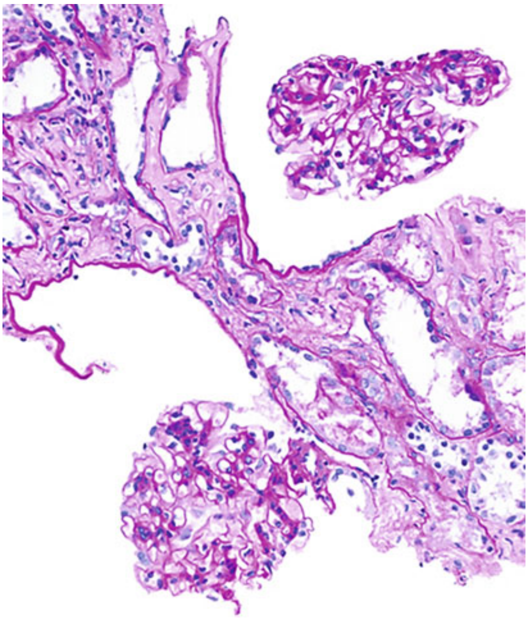

Fig. 3 Typical section of kidney tissue obtained from an 18 g needle biopsy. Bowman's capsule is torn, and the glomeruli are floating (periodic acid-Schiff stain, original magnification 200×)

been a decline in tissue adequacy. Quality improvement efforts in each center can lead to a return to historical norms [21].

Other Biopsy Techniques

Alternatives to percutaneous renal biopsy include open or laparoscopic surgical biopsy and trans-jugular renal biopsy [77]. Likely because the patients requiring these alternatives are at significantly higher risk, the complication rate may in some series be higher than with routine percutaneous biopsy [68]. The surgical biopsy has similar adequacy, but the trans-jugular biopsy is much smaller and fragmented often making analysis difficult [47]. Superficial wedge biopsies from open surgical biopsies may undersample disease-specific lesions and oversample areas of subcapsular scar. Larger, deeper wedges, or needle biopsies should therefore be considered in this setting. The requirement for diagnostic material must significantly outweigh the increased invasiveness of these alternate techniques.

Assessment of the Renal Biopsy

Adequacy of Sample

Cores of fat and connective tissue will float when placed in saline, but a core of renal parenchyma will sink. In diffuse disease, such as membranous glomerulopathy, one glomerulus may be adequate for diagnosis. However, in other diseases, such as crescentic glomerulonephritis, FSGS, or lupus nephritis, diagnostic lesions may be focal. The greater the number of glomeruli sampled, the lower the probability of missing a focally distributed lesion [14]. If only 10% of glomeruli in the kidney are involved by the focal process, a biopsy sample of only 10 glomeruli has a 35% probability of missing the lesion, decreasing to 12% if the biopsy contains 20 glomeruli. When one-fourth of glomeruli are involved in the kidney, there is only a 5% chance of missing the abnormal glomeruli in a biopsy of 10 glomeruli. A biopsy sample of 20–25 glomeruli for light microscopic assessment is sufficient to distinguish between mild disease (less than 20% of glomeruli involved), moderate disease (20–50% of glomeruli involved), and severe disease (more than 50% of glomeruli involved). The sample site must also be considered in evaluating the adequacy of tissue. Even a large biopsy, consisting only of superficial glomeruli, cannot exclude the presence of early FSGS, in which the initial involvement is in the juxtamedullary glomeruli. Likewise, a biopsy containing cortex and juxtamedullary tissue is needed to raise the histopathologic suspicion of nephronophthisis in children and young adults with unexpected chronic kidney disease [40].

Allotment of Tissue

Renal tissue should be studied by light microscopic techniques with special stains (hematoxylin and eosin, modified silver stain [periodic acid/methenamine, also called Jones' stain], periodic acid-Schiff [PAS], and/or Masson trichrome), IF and EM [12, 24, 61, 73]. The tissue is divided so that glomeruli are present in each portion of the sample (Fig. 4). Fixative and transport media should be available in

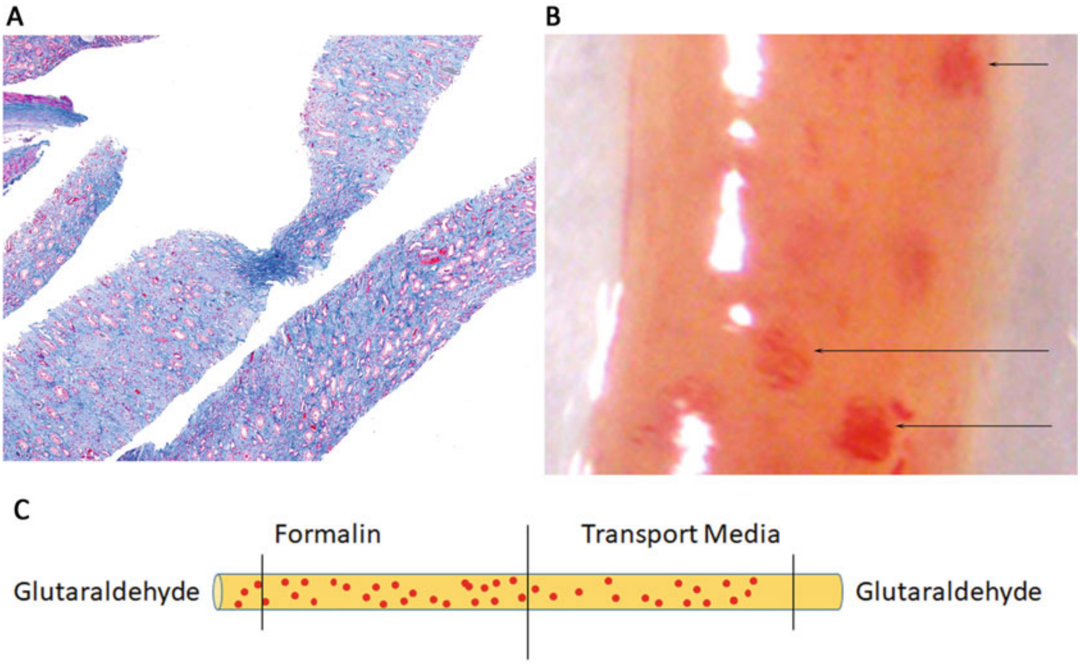

Fig. 4 (**a**) Crush artifact from the use of a forceps to remove the tissue from the biopsy needle (trichrome stain, original magnification 40×). (**b**) Dissecting microscope photograph of a biopsy sample (glomeruli are seen as red balls, arrows, original magnification 15×). (**c**) Schema for optimal allocation of core tissue. Allocate the sample by cutting it with a portion placed in formalin and the remainder in transport media for immunofluorescence (Michel's), after 1 mm cubes are removed from each end and placed in glutaraldehyde (red dots signify glomeruli)

the biopsy suite. The biopsy optimally is timed so that an experienced technician or pathologist can attend to ensure prompt processing of the biopsy tissue. The speed with which the sample is placed in fixative determines the quality of the morphology which can be obtained, particularly for electron microscopy. Thus, each core should be allocated as it is obtained, not waiting until all passes are made. If this is impossible, tissue may be placed in saline and brought directly to the laboratory for processing. After each biopsy pass, the tissue should be carefully removed using a needle or a wooden stick but never a forceps, as the forceps can cause crush artifact (Fig. 4a). The tissue core is places on a clean smooth surface (i.e., wax board) or other nonstick pad (not a gauze pad or sponge, which also causes divoting artifact as the tissue molds to the holes of the underlying surface). The tissue ideally is then examined for the presence of glomeruli using a dissecting microscope or a "smart" phone camera. Glomeruli are identified as red dots and, when present, are identifiable >80% of the time (Fig. 4b). Of note, in severely scarred kidneys or with very low GFR, visualization of glomeruli may be difficult. When a dissecting scope is not available or visualization is not possible, allocation of tissue can then optimally be done by cutting 1 mm pieces off each end of each core for electron microscopy, and dividing each remaining core into two pieces, with the larger portion (about two-thirds of the length of the core) for light microscopy and the remaining small piece for immunofluorescence (Fig. 4c). This approach optimizes chances of glomeruli available for each modality.

When the tissue sample obtained is very small, the nephrologist and the pathologist should consider the differential diagnosis and allocate tissue accordingly. For example, in a case of suspected IgA nephropathy, tissue for IF is most important. IF studies can be attempted on remaining fixed tissue in the paraffin block but are not as reliable as when performed on frozen nonfixed material. Electron microscopic studies can be done on other portions of tissue (as long as mercury-based fixatives have not been used). When tissue for EM is inadequate, portions of the paraffin-embedded tissue left after light microscopic examination may be cut out from the block and processed for EM. Although the quality is not optimal, diagnostic findings can still be discerned. In special circumstances, when no tissue remains in the paraffin block and a focal lesion in one section must be studied, one may attempt to process the tissue section from a glass slide for EM.

Light Microscopy

Numerous fixatives are used for light microscopic examination, and they vary from institute to institute. Satisfactory results may be obtained with Zenker's, Bouin's, or Carnoy's fixatives, formalin, or paraformaldehyde. Material for IF studies may be snap frozen immediately at −20 °C in solutions of isopentane, dry ice, acetone, or Freon and embedded in Tissue-tech, OCT, or other compounds for frozen sections. If tissue cannot immediately be snap frozen, it may be placed in Michel's tissue media, where it may be stored for up to 1 week before freezing. This allows tissue to be sent to reference laboratories for appropriate processing. Tissue for EM may be fixed in glutaraldehyde, formaldehyde, or other appropriate nonmercury fixatives. Tissue placed in glutaraldehyde should be promptly processed, or if stored for future possible processing, should be transferred to an appropriate buffer solution within a week to avoid artifacts. Tissue for LM is routinely processed, embedded in paraffin, and cut into 2- to 3-μ thick sections. Serial sections with multiple levels are then prepared for examination.

If water-soluble compounds are expected, such as urate or uric acid, the tissue should be fixed in ethanol. Lipids are best detected in frozen sections because they are extracted during alcohol and xylene processing for paraffin sections. Hematoxylin and eosin stains are most useful for overall assessment of the interstitium and crystals. This stain also allows particularly good visualization of infiltrating cells, especially eosinophils. In addition, fibrin may be easily visualized by this stain. Additional stains are routinely used for kidney biopsy assessment (Fig. 5). Periodic acid-Schiff (PAS) stains glycoproteins and accentuates basement membranes and matrix material and allows definition of the brush border of proximal tubular cells. Areas of hyalinosis and protein precipitation, including cryoglobulin (which usually is dominantly IgM), are also accentuated with PAS. Silver stains, such as Jones' stain, stain basement membrane material but not cells or deposits, thus allowing distinction of these components. Masson's trichrome stain detects areas of collagen deposition by staining bluish. Sirius red stains all collagens and can also be visualized and quantified under polarized light to assess fibrosis. Other special stains, such as immunohistochemistry for specific molecules, may be indicated. Congo red stain detects amyloid. Special stains can detect bacterial or fungal organisms and acid-fast bacilli. Special techniques may also be used on the light microscopic material. These include polarization to detect crystals or foreign bodies and morphometry to assess glomerular size and severity of interstitial fibrosis quantitatively.

Immunofluorescence Microscopy

Immunofluorescence (IF) studies are most commonly done by direct IF on frozen tissue sections with application of fluorescein-conjugated antibodies directed against IgG, IgA, IgM, complement components C3 and C1q, kappa, lambda, and often albumin and fibrinogen. Additional antisera may be used as clinically indicated. Phospholipase A2 receptor (PLA2R), the antigen in most cases of so-called primary membranous nephropathy (MN), is detected by IF by digestion techniques, followed by applying antibody to PLA2R to tissue section cut from the paraffin block or by IF on frozen tissue [6, 37]. Additional antigens in membranous nephropathy have been identified by mass spectroscopy, and immunofluorescence for immunohistochemistry methods developed for their detection in the deposits of cases of membranous nephropathy [60]. These novel antigens include thrombospondin type 1 domain-containing 7A (THSD7A),

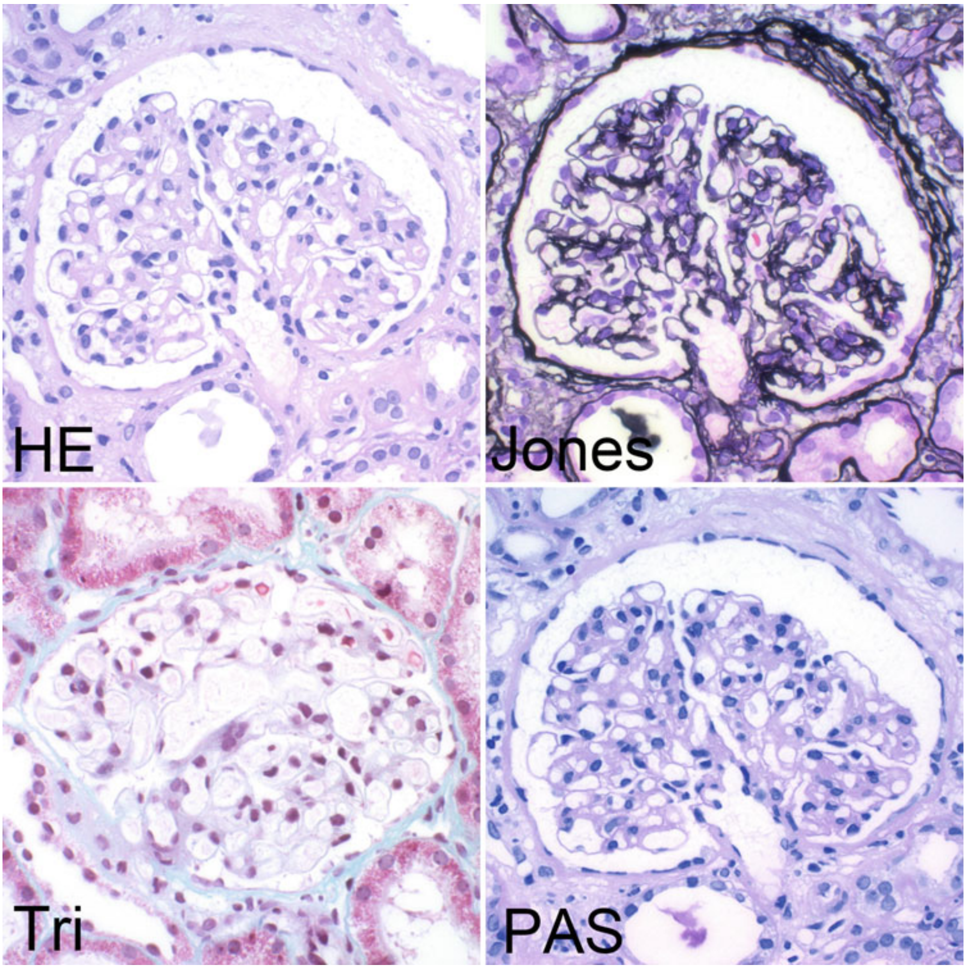

Fig. 5 A normal glomerulus shown with hematoxylin and eosin (H&E), Jones, trichrome (Tri) and periodic-acid Schiff (PAS) staining. These are the principal stains used routinely for the examination of paraffin-embedded tissue in renal pathology (original magnifications ×400)

exostosin-1,2, neural EGF-like-1 NELL-1, and semaphorin 3B (Sema3Band PCDH7) discussed in sections on membranous nephropathy [27, 60].

Additional immunostaining studies include those for hepatitis B antigen, thyroglobulin, C4, C4d, C3d, specific viruses (e.g., SV40 for polyoma virus), myoglobin, and type IV collagen alpha chains. Some of these antigens are recognized by antisera even after fixation and can be detected by immunohistochemical techniques (e.g., immunoperoxidase) on the formalin-fixed tissue sections and then studied with a light microscope. This technique requires enzyme pretreatment of tissue depending on the antigen to be studied, which must be tailored exactly depending on length and type of fixation and section thickness. Direct observation of the digestion process, stopping when all plasma is removed from capillary loops, has been used to achieve reliable results [20]. These challenges have prevented widespread use of this technique for the routine immunostaining panel performed in the USA. In general, IF on frozen tissue for detection of immunoglobulins and complements is more sensitive than IHC or even IF on fixed tissue.

Frozen tissue sections stained by the commonly used method of fluorescein-conjugated antibodies are viewed by IF microscopy, evaluating staining in glomeruli, vessels, tubules, and interstitium. The pattern of glomerular staining is assessed to define granular or linear capillary wall staining or mesangial deposits. Arteriolar staining may be of diagnostic significance to detect, for example, deposits in lupus. Tubules may show granular deposits in lupus nephritis, pseudolinear deposits in light chain deposition disease, or linear staining in the rare anti-TBM antibody disease. Nuclear staining can be seen in lupus or lupus-like diseases as a tissue manifestation of the patient's positive ANA. IF is more sensitive than EM in identifying immune deposits, although EM provides more detailed information on the exact localization of those deposits [24, 61]. Diagnostic lesions of interest should be photographed because fluorescence fades on storage and with light exposure.

If there is no tissue available for IF by frozen section, the paraffin-embedded tissue can be used [46, 49]. This can salvage what would have been a significant biopsy miss. IgA deposits are usually readily detectable by this technique and can allow specific diagnosis of IgA nephropathy in cases where glomeruli are not present in the frozen tissue. In addition, paraffin IF has become a required technique for the correct diagnosis of a specific subset of glomerular diseases in which there may be masked deposits. The finding of a proliferative glomerulonephritis with C3 only with or without a membranoproliferative pattern is consistent with C3 glomerulopathy (C3G, see ▶ Chap. 22, "Membranoproliferative Glomerulonephritis and C3 Glomerulopathy in Children"). However, this is an extremely rare condition requiring a detailed expensive workup. Paraffin IF provides the correct diagnosis by unmasking immunoglobulins and light chains thus ruling out C3G in a significant minority of cases [39, 46]. Staining for tissue-bound C3d, or possibly C4d, in addition to the usual staining for soluble C3c might be useful to distinguish C3 glomerulopathies from immune complex glomerulonephritis, although C4d staining may also be present nonspecifically in normal glomeruli, making interpretation more challenging [57, 58, 65].

Membranous-like glomerulopathy with masked IgG kappa deposits is a specific lesion that requires paraffin IF for diagnosis [38, 41]. This is a disease predominantly of teen and young adult females (but with a wide age spectrum, 10–72 years), which presents with vague autoimmune symptoms. LM reveals segmental membranous glomerulopathy with corresponding segmental membranous-like subepithelial deposits by EM. Routine IF shows C3 only in mesangial and capillary loop regions with rare cases showing trace to 1+ IgG. Paraffin IF demonstrates characteristic IgG and kappa but not lambda staining. Subsequent confirmation can then be done using IHC for serum amyloid P protein [41].

Electron Microscopy

Tissue for EM is processed with post fixation in 1% osmium tetroxide, which enhances contrast of the tissue, and then dehydrated and embedded. With new, more rapidly polymerizing embedding media, such as Spurr, tissue may be ready for examination within 1 day. Ultrasound may further hasten the processing but may cause some artifacts. Electron microscopic study added information in a significant but small number of renal biopsies. In one study, EM was needed to make a diagnosis in 21% of cases and provided important confirmatory data in approximately 20% of cases [24]. EM showed diagnostic pathological abnormalities in 18% of patients with "normal" light microscopic findings. Larger, so-called thick scout sections (1 μ) made from the tissue allocated for EM are stained with toluidine blue to select smaller areas for thin sectioning for direct assessment with the electron microscope. Usually, the glomerulus containing the most representative lesion is chosen, but sclerotic glomeruli are not useful to examine by EM. If there are irregular or focal hypercellular/proliferative lesions, several glomeruli may be sampled, including the proliferative ones. The 60–90 Å thin sections are stained with uranyl acetate and lead citrate to enhance contrast before viewing in the EM scope.

Specific localization of immune complexes is done by EM examination, indicating whether deposits are subendothelial, subepithelial, mesangial, or in all of the above compartments. Immune complex deposits are nonmembrane-bound and denser than basement membrane or matrix materials. In specific diseases, such as cryoglobulinemia, amyloid, immunotactoid or fibrillary glomerulopathies, or lupus nephritis, specific substructure of deposits may be seen. In some diseases, such as light chain deposition disease or lupus nephritis, deposition may also be seen in vessels and tubules. So-called fingerprint deposits, with substructure reminiscent of fingerprinting, are present in some cases of lupus nephritis. Reticular aggregates (or so-called tubular arrays) of organelle membrane material in endothelial cell cytoplasm throughout the body are characteristically seen in large numbers in patients with SLE or HIV infection, or those treated with exogenous interferon, thought to reflect a response to high levels of interferon [61].

EM also delineates specific basement membrane abnormalities. For instance, small subepithelial deposits without surrounding new basement membrane material do not result in spikes and therefore cannot be visualized by Jones' stain on LM but can still be detected directly by EM. The lamina densa of the GBM is markedly thickened in diabetic nephropathy. Circumferential cellular interposition is defined by extension of monocytes and mesangial cell cytoplasm into the subendothelial space, with newly formed basement membrane interpositioning between the advancing infiltrating cells and the endothelium with intervening basement membrane material, thus giving rise to the classic double contours seen with silver stain by LM in MPGN. Increased lucent material is present in the expanded lamina rara interna in transplant glomerulopathy, HUS, eclampsia/preeclampsia, and other diseases presumed to involve endothelial injury/coagulopathy (see Chaps. "Renal Involvement in Children with Hemolytic Uremic Syndrome (HUS) and Thrombotic Thrombocytopenic Purpura (TTP)," and ▶ 24, "Infection-Related Hemolytic Uremic Syndrome (HUS)"). In these conditions, deposition of fibrin, fibrinogen, and their degradation products and/or accumulation of platelets may also occur. Fibrin is recognizable by its dense, coarse sheaflike structure by EM, with periodicity observed in favorable sections. Morphometry of the GBM from EM images is used to diagnose thin basement membranes in hereditary nephritides (see ▶ Chap. 13, "Inherited Diseases of the Glomerular Basement Membrane"). EM also allows structural assessment of changes of specific cells. Diagnostic inclusions are seen in various storage/metabolic disease, such as Fabry's disease.

Normal Kidney Morphology

During fetal maturation, the glomerular capillary tufts are initially covered by large, cuboidal, darkly staining epithelial cells with only small lumina visible (Fig. 6). The cells lining Bowman's space undergo similar change from initial tall columnar to cuboidal to flattened epithelial cells, except for those located at the opening of the proximal tubule, where cells remain taller. Immature nephrons may occasionally be seen in the superficial cortex of children up to 1 year of age. Glomerular growth continues until adulthood, with average normal glomerular diameter approximately 95 μ in a group of patients less than 5 years old (average age 2.2 years) and 140–160 μ in adulthood [17, 30, 67].

The normal mature glomerulus consists of a complex branching network of capillaries originating at the afferent arteriole and draining into the efferent arteriole. The glomerulus contains three resident cell types: mesangial, endothelial, and epithelial cells (Figs. 7 and 8). The visceral epithelial cells (podocytes) cover the urinary surface of the GBM with pseudopodlike extensions called foot processes, with intervening filtration slits. Endothelial cells are opposed to the inner surface of the GBM and are fenestrated. At the stalk of the capillary, the endothelial cell is

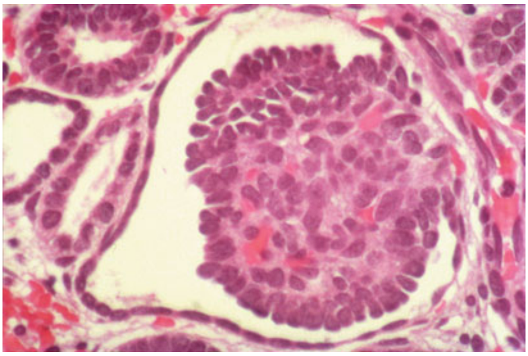

Fig. 6 Immature glomerulus with plump, dark epithelial cells from biopsy of a 29-week-gestation baby (PAS, original magnification ×670)

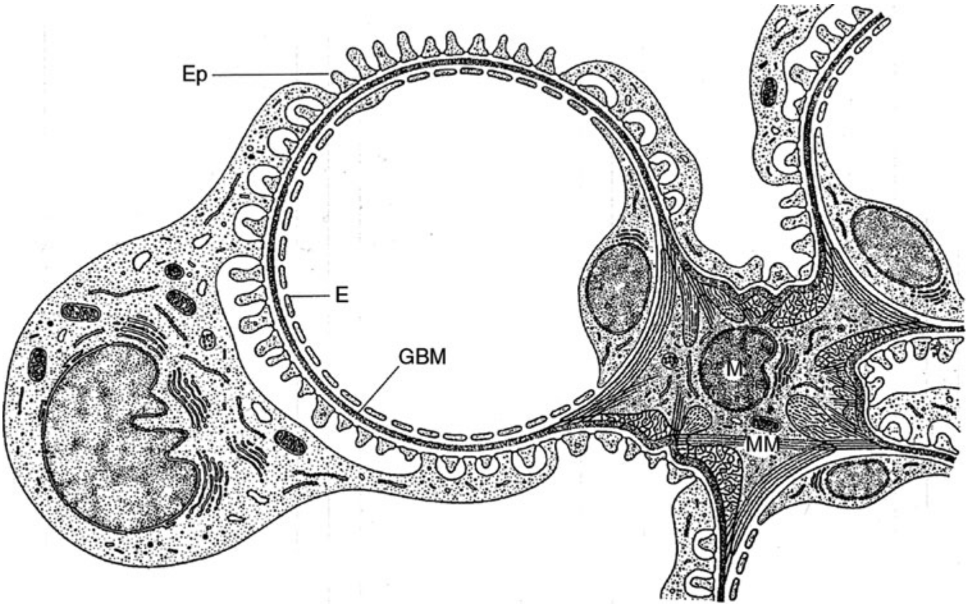

Fig. 7 Schematic illustration of glomerulus, with glomerular capillary attached to a mesangial stalk area. The glomerular endothelium (*E*) is fenestrated and lines the glomerular basement membrane (*GBM*), which covers the mesangium. The outside of the GBM is covered by the epithelial cell and its foot processes (*Ep*). The mesangial cell (*M*) is embedded within the mesangial matrix (*MM*), with processes connecting to the GBM (Provided courtesy of Professor Wilhelm Kriz)

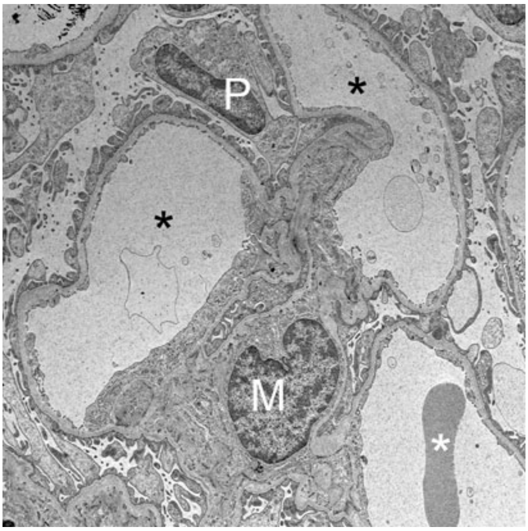

Fig. 8 A normal glomerulus examined by transmission electron microscopy. There are three capillary loops with the capillary lumina marked by black *, with red blood cells marked by a white *. A podocyte nucleus on the outside of the glomerular basement membrane with interdigitating foot processes is marked with a P. The inside of the glomerular basement membrane is lined with fenestrated endothelium. A mesangial cell (M) lodges in the mesangial stalk, anchoring the capillary loops (transmission electron microscopy, original magnification ×2000)

separated from the mesangial cells by intervening mesangial matrix. The term *endocapillary* is used to describe hypercellularity/proliferation filling up the capillary lumen, contributed to by proliferation of mesangial, endothelial, and infiltrating inflammatory cells. In contrast, *extracapillary* hypercellularity/proliferation refers to an increased number of parietal epithelial cells that line Bowman's capsule, resulting in a crescent lesion.

The mesangial cell is a contractile cell that also has phagocytic properties. It lies embedded in the mesangial matrix in the stalk region of the capillary loops, attached to anchor sites at the ends of the loop by thin extensions of its cytoplasm. Normally up to three mesangial cell nuclei per lobule are present. The basement membrane consists of three layers distinct by EM, the central broadest lamina densa and the less electron-dense zones of lamina rara externa and interna. Thickening occurs with maturational growth. Most investigators have found thicker basement membranes in boys, with normal range from 220 to 260 nm at 1 year of age, 280 to 327 nm at age 5 years, 329 to 370 nm at age 10 years, and 358 to 399 nm at age 15 years [48]. In our laboratory, we found a range

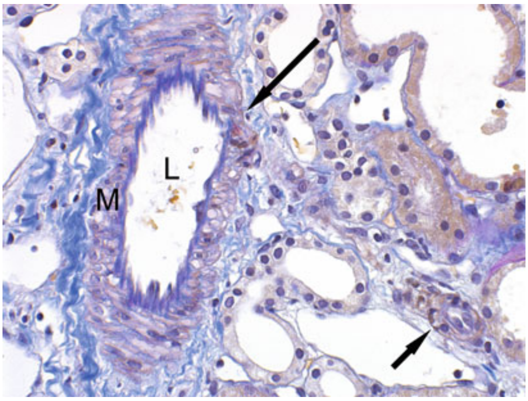

Fig. 9 A normal artery is shown on the left, marked by the long arrow, with the lumen (L) and the media (M). Arteries are distinguished from arterioles (short arrow) by having at least two layers of smooth muscle cells in the media (trichrome-elastica, original magnification ×400)

of GBM thickness in children with normal kidneys from approximately 110 nm at age 1 year to 222 ± 14 nm at 7 years of age.

The glomerulus is surrounded by Bowman's capsule, which is lined by parietal epithelial cells. These are continuous with the proximal tubule. The efferent and afferent arterioles can be distinguished morphologically in favorably oriented sections or by tracing their origins on serial sections. Segmental, interlobular, and arcuate arteries may also be present in the renal biopsy specimen (Fig. 9). The cortical biopsy also allows assessment of the tubules and interstitium. Proximal tubules are readily identified by their PAS-positive brush border, lacking in the distal tubules. Collecting ducts show cuboidal, cobblestone-like epithelium. Tubules are normally back-to-back with minimal interstitial cells and the peritubular capillaries intervening (Fig. 10a). The medulla may also be included in the biopsy.

Patterns of Injury

Overall Pattern

Assessment of the biopsy specimen must include inspection of all sections from different levels because additional glomeruli may be sampled on deeper cuts of the biopsy core and many diseases are characterized by focal lesions [9]. The severity and patterns of lesions are assessed, and normal and affected glomeruli are counted. Lesions are classified as focal if only some (or less than half) glomeruli are involved, diffuse if all (or most) glomeruli are involved, segmental if only portions of glomeruli are involved, and global if entire glomerular tufts are involved. Characteristic glomerular disease patterns include lobular hypercellularity with double contours of the GBM in MPGN, nodular sclerosis with increased mesangial cells, and abundant matrix material in characteristic Kimmelstiel-Wilson lesions in diabetic nephropathy, focal and segmental sclerosis, intraglomerular/arteriolar fibrin thrombi, necrotizing lesions, and crescent formation (Table 1) [25]. The crescent, a lesion due to increase of mostly parietal epithelial cells, owes its name to its shape in well-established lesions.

Glomeruli are assessed for alterations in size (see below). It is important to compare with a normal control for a given age group because marked glomerular maturational growth occurs in children. Glomerular hypertrophy may be an important predictor of increased risk for ultimate development of FSGS in children with apparent minimal change disease (MCD) [17] (see ▶ Chaps. 14, "Steroid-Sensitive Nephrotic Syndrome," and ▶ 15, "Non-genetic Forms of Steroid-Resistant Nephrotic Syndrome"). Maturational pattern of glomeruli (see above) should be noted. Occasional fetal glomeruli may be found in children beyond infancy and are not of specific diagnostic significance.

Glomeruli are assessed for glomerulosclerosis, that is, the presence of segmental obliteration and scarring of glomerular capillary tufts. Sclerosis may be in a segmental or global pattern (Table 1). Previous studies suggested that up to 10% of glomeruli may be normally globally sclerosed in people younger than 40 years of age [33]. This number may be even smaller in children, with less than 1–3% global sclerosis expected normally up to age 40 or 56, respectively [34, 64]. These occasional globally sclerotic glomeruli are thought to represent errors of nephrogenesis. The percentage of global sclerosis increases even with normal aging, up to half the patient's age, minus 10 [64]. Globally sclerosed glomeruli in greater percentage indicate the possibility of renal disease (focal global sclerosis).

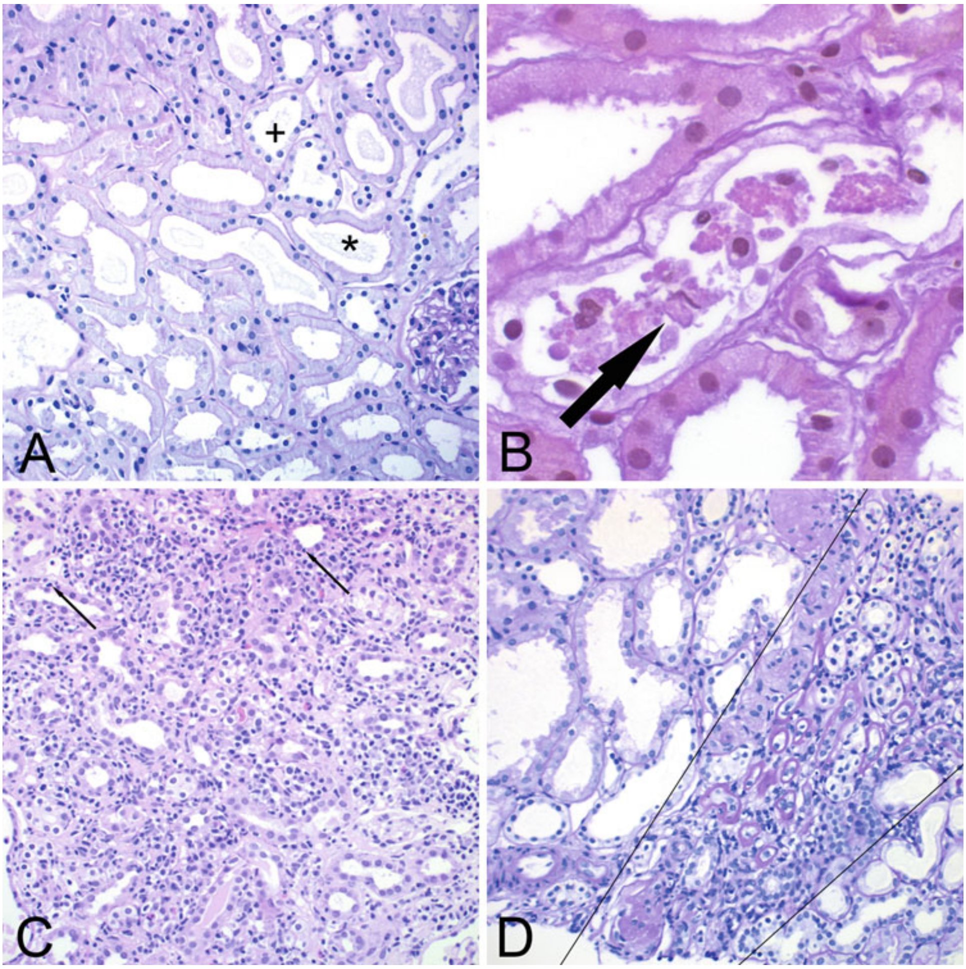

Fig. 10 Normal tubules and tubules in various injuries. (**a**) Normal cortical tubules with proximal segments (*) showing a well-developed periodic acid-Schiff-positive brush border and a distal segment (marked with +) without brush border (PAS, original magnification ×200). (**b**) Acute tubular damage with cellular debris in the lumen (arrow) and flattened tubular epithelium with attenuated brush border (trichrome, original magnification x630). (**c**) Acute tubulointerstitial nephritis with edema and infiltrate of lymphocytes, histiocytes, plasma cells, and eosinophils surrounding and infiltrating tubules (tubulitis) with acute tubular injury (arrows) (H&E, original magnification ×200). (**d**) Focal cortical tubular atrophy and interstitial fibrosis outlined by two black lines. These atrophic tubules have much smaller diameter compared to the surrounding tubules and thicker basement membranes and are surrounded by fibrotic, expanded interstitium with mononuclear infiltrates (PAS, original magnification ×200)

Selected Specific Patterns of Injury

Mesangial Hypercellularity

Hyperplasia of mesangial cells is defined as more than three mesangial cell nuclei present per mesangial region, in areas away from the vascular pole (Fig. 11). Increased mesangial prominence may be due to increased cellularity, increased matrix, deposits, or a combination. Large mesangial deposits appear on Jones' stain as pinkish areas surrounded by the light silver-staining areas of mesangial matrix. So-called interposition results when monocyte or mesangial cell cytoplasm extends outward between basement membrane and endothelial cells and new matrix accumulates between the mesangial and endothelial cell bodies.

Table 1 Definitions of common morphological terms (Modified from [25])

Light microscopy	
Focal	Involving some glomeruli (some definitions use this term for lesions involving <50% of, e.g., glomeruli)
Diffuse	Involving all glomeruli (some definitions use this term for lesions involving ≥50% of, e.g., glomeruli)
Segmental	Involving part of glomerular tuft (some definitions use this term for lesions involving <50% of the glomerular tuft)
Global	Involving total glomerular tuft (some definitions use this term for lesions involving ≥50% of the glomerular tuft)
Lobular	Simplified, lobular appearance of capillary loop architecture (MPGN)
Nodular	Rounded accumulation of collagenous matrix expanding one or more mesangial areas (e.g., in diabetic nephropathy)
Sclerosis	Obliteration of capillary loop by increased matrix (scarring)
Crescent	Extracapillary hypercellularity composed of mostly parietal epithelial cells, involving >10% of the capsular circumference, more than two cell layers thick
Spikes	Projections of glomerular basement membrane intervening between subepithelial immune deposits (e.g., in membranous GN)
Endocapillary proliferation/ hypercellularity	Increased cells within capillary lumens causing luminal narrowing or occlusion
Hyaline	Descriptive of glassy, smooth-appearing material
Hyalinosis	Hyaline-appearing (glassy, smooth) PAS positive, silver negative, amorphous, eosinophilic insudation, composed mainly of plasma components (in, e.g., glomeruli in focal segmental glomerulosclerosis or in arterioles in, e.g., hypertension or diabetes)
Mesangium	Stalk region of capillary loop with mesangial cells surrounded by matrix
Subepithelial	Between podocyte and glomerular basement membrane
Subendothelial	Between endothelial cell and glomerular basement membrane
Tram-track	Two or more contours of glomerular basement membrane due to deposits and/or interposition of cells (see below)
Wire loop	Thick, rigid appearance of capillary loop due to large subendothelial deposits, seen by LM
Activity	Extent of possible treatment sensitive lesions, based on, e.g., extent of cellular/ fibrocellular crescents, cellular infiltrate, necrosis, proliferation
Chronicity	Extent of probable irreversible lesions, based on, e.g., extent of tubular atrophy, interstitial fibrosis, fibrous crescents, glomerulosclerosis
Immunofluorescence microscopy	
Granular	Discontinuous flecks of staining along capillary loop producing granular pattern
Linear	Smooth continuous staining along capillary loop
Electron microscopy	
Foot process effacement	Flattening of foot processes of podocytes so that they cover the basement membrane with loss of slit diaphragm junctions
Microvillous transformation	Small extensions of podocytes with villus-like appearance
Interposition	Extension of cell cytoplasm with interposition between endothelial cell cytoplasm and basement membrane and underlying new basement membrane formation
Reticular aggregates	Organized arrays of interlacing, curved tubular structures within the endoplasmic reticulum cisternae in endothelial cells
Immunotactoid GP	Large, organized microtubular deposits, >30 nm diameter
Fibrillary GP	Fibrils 14–20 nm diameter without organization (usually DNAJB9 positive by IHC)

GP glomerulopathy, *IHC* immunohistochemistry, *MPGN* membranoproliferative glomerulonephritis

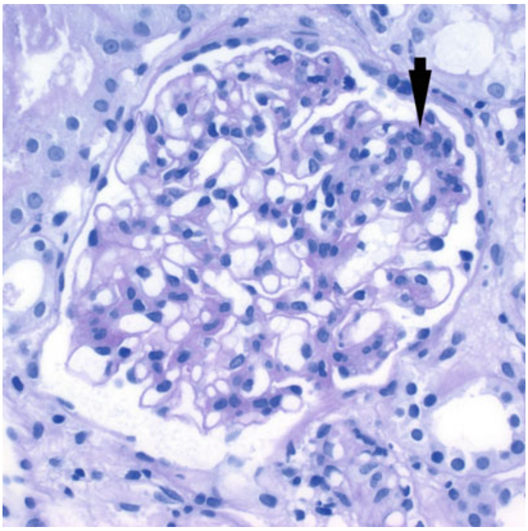

Fig. 11 Segmental mesangial hypercellularity (arrow), defined as a cluster of more than 3 mesangial cells, recognized by being surrounded by mesangial matrix, in a mesangial area (PAS, original magnification ×400)

Endocapillary Hypercellularity/Proliferative Lesions

Endocapillary cell hypercellularity/proliferation (defined as increased number of cells within the capillary lumen, causing significant narrowing of the capillary or occlusion) is characteristic of for example diffuse proliferative lupus nephritis and the MPGN pattern (Fig. 12). This pattern most often is a response to subendothelial deposits. The specific diagnosis requires IF and EM studies and integrated clinicopathologic interpretation.

Membranoproliferative Pattern

The glomeruli show a lobular appearance, with mesangial and often endocapillary hypercellularity (see above) and double contours of the GBM (Fig. 13). This is often caused by subendothelial deposits with interposed cells reacting to the deposits but may also result from chronic endothelial injury with increased lamina rara interna and interposed cells without deposits (i.e., chronic TMA, or more correctly, chronic microangiopathy without thrombosis). The deposits may be due to immune complexes, C3 glomerulopathy, monoclonal protein, or other entities. Thus, IF and EM are crucial to distinguish the cause of MPGN pattern lesions.

Exudative Pattern

This describes a hypercellular glomerulus with prominent inflammatory cells including frequent PMNs narrowing or occluding capillary lumens and is most often seen in infection-related immune complex GN (Fig. 14).

Crescents

Crescents consist primarily of proliferating parietal epithelial cells with some infiltrating macrophages and are a manifestation of severe glomerular injury (Fig. 15). The name reflects the often crescent-shaped sheet of cells filling up part or nearly all of Bowman’s space. Crescents result from injuries that break the GBM, leading to exudation of plasma protein and formation of fibrin within Bowman’s space, which then induces proliferation of the parietal epithelial cells and infiltration of macrophages. When crescents are a prominent histologic feature, the patient most often presents clinically with a rapidly progressive glomerulonephritis. Crescents may occur in a variety of diseases. Diseases with crescents as a primary manifestation include antibody-mediated injury (anti-GBM antibody disease), severe immune-complex diseases (e.g., lupus nephritis), and pauciimmune diseases, the latter most often ANCA positive. The early lesion of cellular crescents is responsive to cytotoxic therapy. Biopsy indications of irreversible renal damage include breaks of Bowman’s capsule [10] and fibrous transformation of the cellular crescents, periglomerular fibrosis, and scarred glomeruli and tubulointerstitium.

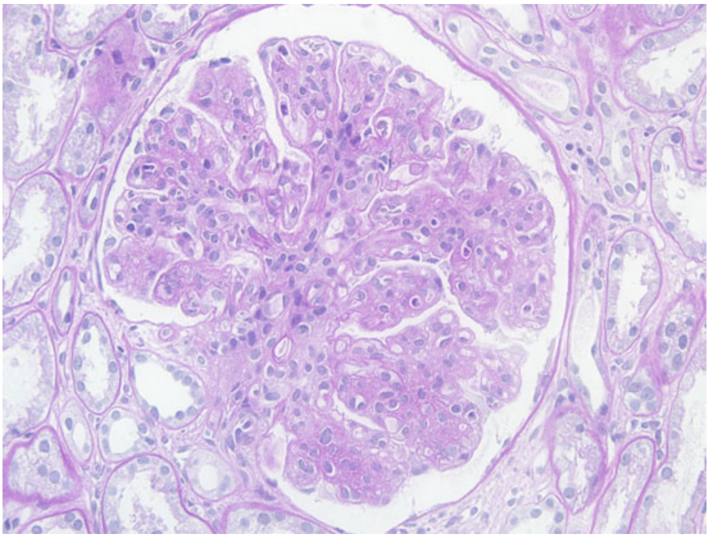

Fig. 12 Global endocapillary hypercellularity which is defined as increased number of cells within capillary lumens causing luminal narrowing or occlusion (PAS, original magnification ×400)

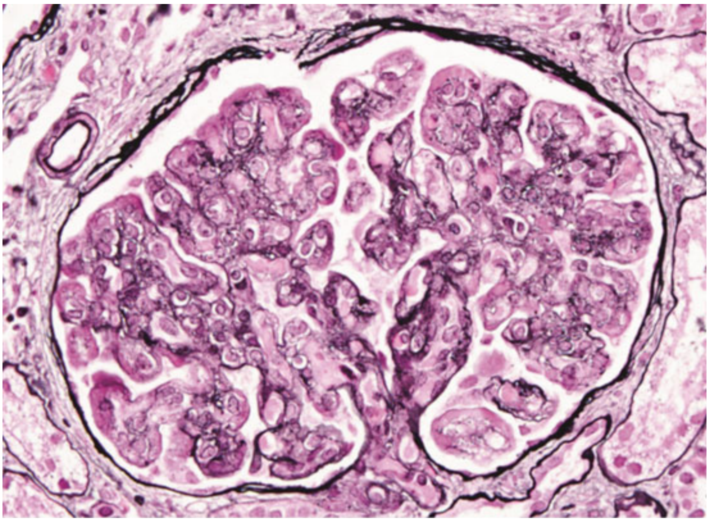

Fig. 13 Double contours of the glomerular basement membrane ("tram-tracking") in membranoproliferative glomerulonephritis (MPGN), caused by subendothelial/intramembranous deposits and cellular interposition (Jones' silver stain, original magnification ×400)

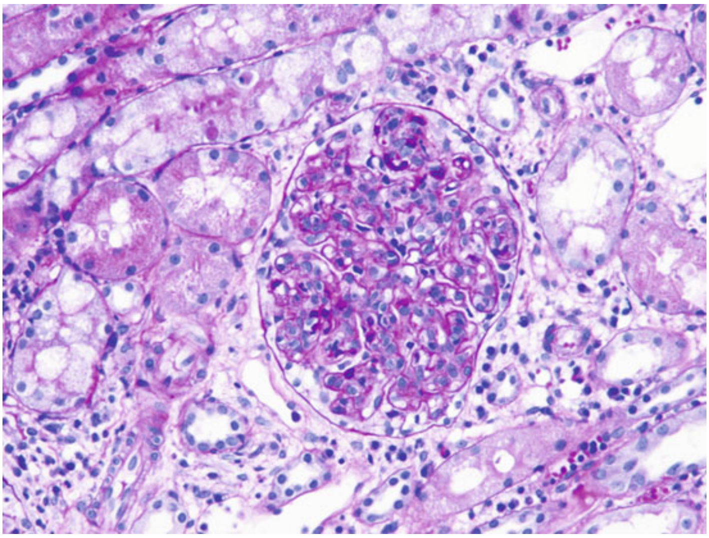
Segmental Sclerosis

Segmental sclerosis refers to sclerosis of a portion but not the whole glomerulus (Fig. 16). In contrast, global sclerosis refers to sclerosis of the entire tuft, and when present in an obsolescent pattern is nonspecific and can occur at any age, even in normal young children. Segmental sclerosis of classic type is defined as obliteration of the capillary lumen by increased matrix. There may be associated hyalinosis, defined as insudation of components of plasma, including lipids, which stain PAS positive and appears glassy smooth (hence the term hyaline. Foam cells may be present. Segmental sclerosis can happen due to any chronic glomerular injury and specific diagnosis must be made with integration of sclerosis type, immunofluorescence, and electron microscopy findings and clinical setting (see sections on specific diseases).

Thrombosis

Thrombosis may involve glomeruli or the vasculature, including arterioles and arteries, and is

Fig. 14 Postinfectious glomerulonephritis with endocapillary hypercellularity/proliferation and neutrophil infiltration (PAS, original magnification ×430)



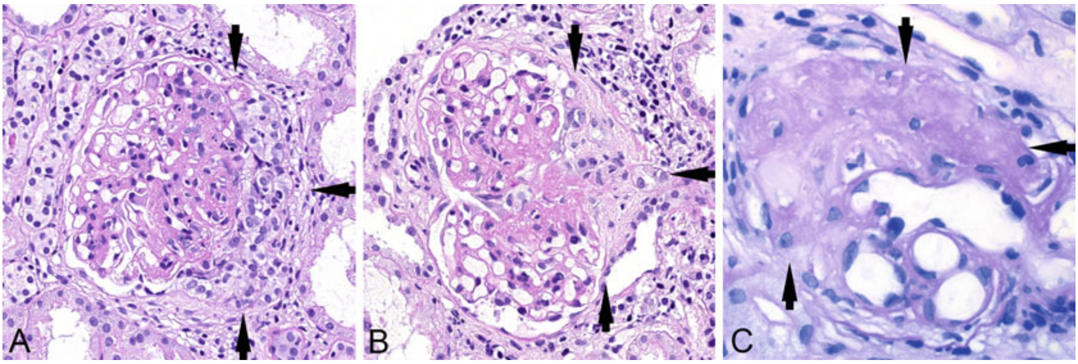


Fig. 15 Stages of crescents, defined by extracapillary hypercellularity surrounding the glomerular tuft (**a**) A cellular crescent (arrow), an active lesion, defined as consisting of more than two cell layers, with more than 75% of the crescent composed of cells (PAS, original magnification ×400). (**b**) Fibrocellular crescent (arrows), the intermediate stage of organization and scarring, with 25–75% of the crescent composed of cells, and the remainder of matrix (PAS, original magnification ×400). (**c**) Fibrous crescent, the most advanced stage, composed of at least 75% matrix, with correspondingly decreased cellular content. Note the four remaining capillary lumina (PAS, original magnification ×630)

defined as intralumenal fibrin thrombi composed of fibrin, platelets, and coagulated blood (Fig. 17). The term thrombotic microangiopathy has also been used to describe associated vascular lesions with fibrinoid necrosis within the wall, but not in the lumen, or chronic microangiopathy changes without fibrin, better called microangiopathy without thrombosis (see ▶ Chaps. 21, "Autoantibodies and Kidney Diseases," "Renal Involvement in Children with Hemolytic Uremic Syndrome (HUS) and Thrombotic Thrombocytopenic Purpura (TTP)," and ▶ 24, "Infection-Related Hemolytic Uremic Syndrome (HUS)") [22].

Acute Tubular Injury

Morphologically evident acute tubular injury or necrosis correlates poorly with the clinical extent of acute kidney injury (AKI) (Fig. 10b). The changes vary from nondiagnostic vacuolization to frank necrosis with sloughing of tubular epithelial cells (toxic type) and flattened epithelium

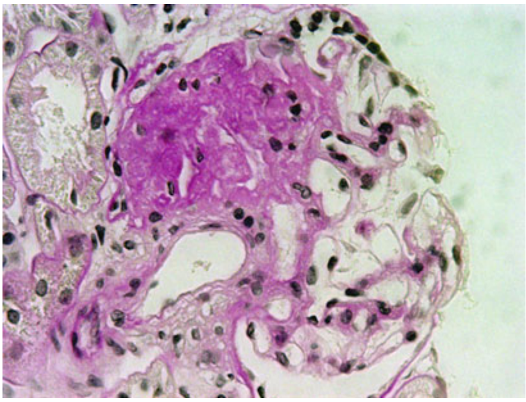

Fig. 16 Segmental sclerosis, with a portion of the tuft showing obliteration of the capillary lumens by matrix (PAS, original magnification ×400)

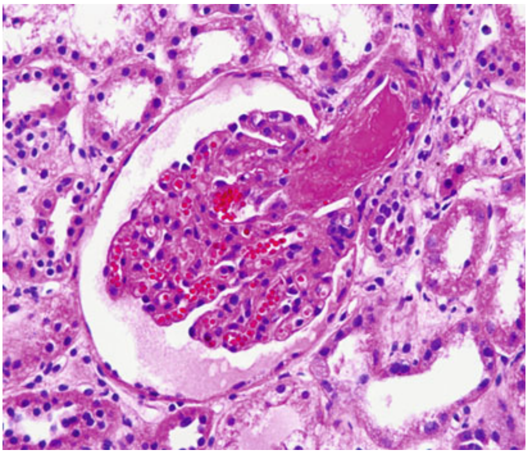

Fig. 17 Arteriolar fibrin thrombi with congestion in capillary loops, characteristic of the thrombotic microangiopathy seen in hemolytic uremic syndrome (Jones' stain, original magnification ×270)

characteristic of regeneration (ischemic type). In cortical necrosis, zones of cortex, including glomeruli, are necrotic.

Interstitial Fibrosis/Tubular Atrophy (IFTA)

In chronic kidney disease, tubules are atrophied with dilation and flattened epithelium (Fig. 10d). IFTA may occur secondary to lesions affecting the glomerulus, although primary tubular and interstitial injury mechanisms may also cause IFTA. Increased IFTA is associated with worse prognosis regardless of its cause [55]. Fibrosis results in increased spacing of tubules because of the accumulation of PAS-positive collagenous material, with thickened tubular basement membranes. The collagen also stains specifically blue with Masson's trichrome stain. Fibrosis in a striped pattern suggests calcineurin inhibitor toxicity or other causes of ischemia (e.g., renal artery stenosis), with the striped pattern reflecting particular susceptibility of the medullary rays to such hypoxic injury (see ▶ Chap. 81, "Renal Transplantation: Immunosuppression and Managing Allograft Rejection"). Acute tubular injury may result in regeneration, or if cell cycle arrest occurs, develop into IFTA lesions.

Acute Interstitial Nephritis

Interstitial edema is a nonspecific change, present, for example, in early acute transplant rejection, renal vein thrombosis, or inflammatory processes. Acute interstitial nephritis (AIN) is defined as edema and lymphoplasmacytic infiltrate, with variable components of other inflammatory cells (Fig. 10c). Eosinophils in an infiltrate are suggestive of drug-induced/hypersensitivity interstitial nephritis, although eosinophils are also present in some cases of idiopathic interstitial nephritis and in diabetic nephropathy with IFTA [54]. Of note, the lack of eosinophils does not exclude hypersensitivity as the etiology of the AIN. Eosinophils can also be part of acute cellular rejection in the transplant. Nonnecrotizing granulomas, with or without eosinophils, most often reflect drug-induced hypersensitivity reaction. A pleomorphic infiltrate of lymphocytes, plasma cells, and PMNs suggests possible polyoma virus nephropathy in the transplant, confirmed by finding viral nuclear inclusions and positive immunostaining in tubules. Polyoma virus can also cause tubulocentric granulomas in some cases. Plasma cell-rich infiltrates with a whorling storiform fibrosis pattern suggest IgG4-associated interstitial nephritis.

Prognostic Implications of Biopsy Findings

When the biopsy sample is adequate, extensive, severe, and irreversible lesions signify a dismal prognosis for the patient. Globally sclerotic glomeruli are not amenable to treatment, although evidence from human diabetic nephropathy and animal studies indicates that the earlier stages of sclerosis may be affected by some therapeutic interventions and may even be reversible. Similarly, active lesions with ongoing cellular crescents, necrosis, and inflammatory infiltrates are potentially dramatically modulated by therapy, allowing subsequent healing. There may be minimal irreversible damage to glomerular structures when intervention occurs early.

Although the renal biopsy may yield a diagnosis, there is less information about prognostic indicators in diseases that have a variable course. Extensive analysis aimed at determining histologic features associated with poor prognosis has been done in some diseases, discussed in specific sections. The best prognostic indicator in one study of lupus nephritis was the proportion remaining of intact glomeruli in follow-up biopsies [28].

New Methods for the Future

With the recent surge of the application of molecular biology techniques to the study of renal disease, candidate factors involved in pathogenesis and progression of disease are being studied in animal models. Studies in human beings have also commenced. With further development of such studies, we may identify specific abnormal processes and thus target therapy more specifically. Research techniques that have been advantageously applied to elucidate pathogenesis of disease include immunostaining; identifying the specific antigen in deposits of membranous glomerulopathy; light chains or paraproteins in plasma cell dyscrasia-associated diseases; identification of the specific type IV collagen abnormality in Alport syndrome; C4d as a marker of antibody-mediated rejection, novel insights into C3 glomerulopathies and elucidation of pathogenesis of specific *E. coli*-associated toxins in some forms of HUS.

Current studies are aimed at understanding disease etiologies and mechanisms at a molecular and proteomic level, studying renal biopsies by laser capture microdissection (LCM), with mass spectrometry, real time reverse transcription polymerase chain reaction (RT-PCR), and in situ hybridization techniques including nanostring technology [19, 45, 56, 59, 75]. Recent efforts have expanded use of these techniques to study mechanisms of injury and progression. Assessment of the so-called “Increased Expression of Thoroughly Validated Gene Transcript/Classifiers in the Biopsy Tissue Strongly Associated with AMR,” although not officially endorsed, may help in the diagnosis of antibody-mediated rejection [52]. Modulation of growth factors, collagens, cytokines, chemokines, and their receptors has been investigated molecularly in renal biopsies. Single cell RNA seq from kidney tissue and even urine is elucidating new cell types of the normal kidney and novel pathways in disease [2, 76]. Such approaches can offer exciting new mechanistic insights into renal diseases.

In parallel, genetic studies are targeted both at diagnosis and identifying patients at risk for progression in diseases with a variable course. Genetic screening for key podocyte-related mutations is often done in children with FSGS. Autosomal dominant tubulointerstitial diseases often do not show distinct pathologic features, and genetic studies are necessary for precise diagnosis. Noninvasive urinary proteomic and microvesicle studies are also being explored to identify particular signature patterns indicative or predictive of specific lesions or risks [2].

Together these approaches promise to map risks and mechanisms of disease initiation and progression and point to targets to achieve resolution of injury. Sequential biopsies with evaluation of changes in structure and patterns of abnormal factors and modulation by therapy may be necessary to fully understand pathogenesis. Instead of diagnoses of morphologic patterns recognized by current techniques in the renal biopsy specimen, molecular techniques may allow more precise diagnosis of the specific diseases and identification of injury mechanisms.

Abstract

Hematuria and proteinuria are among the common reason why children are referred to a pediatric nephrologist. The initial step in a child with hematuria is to establish the diagnosis by performing a urine microscopy to look for the presence of >5 RBC/microliter in a fresh uncentrifuged urine specimen. The prevalence of isolated hematuria is reported to be 0.4–0.5% in large epidemiological studies. There is increasing evidence that persistent hematuria, particularly if associated with proteinuria, is a risk factor fo chronic kidney disease in the longer term. Therefore, careful history and clinical examination is important so that appropriate investigations are undertaken to identify the

etiology. Glomerular causes of hematuria (glomerulonephritis and familial hematuria) are more common in children than lower tract causes of hematuria (cystitis and hypercalciuria). There is increasing role for genetic testing in children with hematuria, particularly where there is family history of hematuria, deafness, or chronic kidney disease. Imaging (ultrasound and CT scan) is important if urolithiasis or a structural abnormality is suspected.

Proteinuria can be nonpathological (febrile, exercise, or orthostatic) or pathological. Children with persistent proteinuria can be asymptomatic or they can present with nephrotic syndrome. Spot first morning urine sample for urine protein: creatinine ratio (PCR), or albumin: creatinine ratio (ACR) is the ideal test to confirm the presence of proteinuria. Children with urine PCR >50 mg/mmol (>1 g/1.73m^2/day) merit further evaluation in order to exclude significant pathology like primary or secondary glomerulonephritis. Renal biopsy should be considered in children with persistent proteinuria, especially if it is associated with hematuria, reduced GFR, or hypertension.

Approach to the Child with Hematuria

Introduction

Hematuria is a common finding in children. It is defined as the presence of increased red blood cells (RBC) in the urine. The definition varies according to the mode of detection, that is, greater than 5 RBC/microliter in a fresh uncentrifuged midstream urine specimen and greater than 3 RBC/high power field in a centrifuged sediment from 10 ml of freshly voided midstream urine.

Hematuria may either be macroscopic or microscopic. Macroscopic hematuria may appear as red, smoky dark brown, or cola-colored urine. Other causes of pigments in the urine must be considered as differential diagnoses. Dark brown or black urine could be due to bile pigments, methemoglobinemia, alanine, cascara from the dried skins of the coffee fruit, drugs such as resorcinol and thymol, alkaptonuria, and tyrosinosis. Red or pink urine could be due to free hemoglobin, myoglobin, porphyrins, high concentration of urates, foods such as beetroot, blackberries, dragon fruit and red dyes, and drugs including benzene, chloroquine, desferoxamine, phenazopyridine, and phenolphthalein. Microscopic hematuria on the other hand is usually first suggested by the presence of "blood" on a urine dipstick examination. Oxidation of the chromogen tetramethylbenzidine on the dipstick by hemoglobin peroxidase in the presence of hemoglobin or myoglobin results in a green-blue color. This test is very sensitive and can detect as little as 150 microgram/liter of free hemoglobin. Unfortunately, false positive results are common, and is usually due to oxidizing agents present in the urine in particular microbial peroxidases associated with urinary tract infection.

Epidemiology

Epidemiological studies on the prevalence of hematuria in school-aged children indicate that 0.5 to 1% of them will have hematuria detected on two or more occasions, with at least one-third persistent beyond 6 months [1–5]. Large-scale screening programs primarily from Asia involving 350,000 school children from Japan [4] and 40,000 from China [6] reported isolated hematuria in 0.4–0.52%, while 0.03–0.7% of children had both hematuria and proteinuria. In another study involving 1 million young persons aged 16 through 25 years, undergoing medical examination for military service in Israel, persistent isolated microhematuria was found in 0.3%, with males being affected twice as commonly as females [7].

There is increasing evidence from epidemiological studies that hematuria is a risk factor for progression of chronic kidney disease [8, 9]. Evaluation of persistent hematuria with or without proteinuria by renal biopsy identified glomerulonephritis as a cause in 25.4–52.3% [4, 10, 11]. Adverse kidney events, defined by development of proteinuria, hypertension, or impaired kidney function, were observed over a two- to ten-year follow-up period in 6% of children with asymptomatic isolated microscopic hematuria, while 28% of those with hematuria and proteinuria had evidence of progressive kidney disease [11]. Data from the large population-based registry in Israel showed an increased risk of end-stage kidney disease attributable to glomerular disease in adolescents and young adults with isolated microhematuria compared to those without, with incidence rates of 19.6 versus 0.55 per 100,000 patient-years, respectively [7]. The fraction of treated end-stage kidney disease attributed to microscopic hematuria was 4.3% (95% CI, 2.9–6.4%) in that study.

Etiology

Hematuria may originate from the glomeruli, renal tubules and interstitium, or urinary tract (including collecting systems, ureters, bladder, and urethra). In children, glomerular causes of hematuria occur more commonly than non-glomerular. Table 1 outlines the various causes of hematuria. Hematuria can be macroscopic or microscopic.

Table 1 Causes of hematuria classified as of glomerular or non-glomerular origin

Glomerular Hematuria
Familial hematuria syndromes
Thin basement membrane nephropathy
Alport syndrome
Hereditary angiopathy, nephropathy, aneurysms, muscle cramps syndrome
MYH9 syndromes (associated thrombocytopathies)
C3 glomerulopathy
Glomerulonephritis
Postinfectious glomerulonephritis
Membranoproliferative glomerulonephritis
Membranous nephropathy
Crescentic glomerulonephritis
IgA nephropathy
IgA vasculitis nephritis (Henoch-Schonlein nephritis)
Lupus nephritis
Necrotizing vasculitis
Hemolytic uremic syndrome
Non-glomerular Hematuria
Urinary tract infection (bacterial, viral and parasitic)
Hypercalciuria
Urolithiasis
Trauma
Exercise-induced
Chemical cystitis
Cystic kidney disease
Vascular malformations
Nutcracker syndrome
Papillary necrosis
Renal infarction
Malignancies
Nephroblastoma (Wilms tumor)
Renal cell carcinoma
Rhabdomyosarcoma of the bladder
Bleeding disorders
Renal vein thrombosis
Menarche
Factitious

Lower urinary tract causes of gross hematuria include hemorrhagic cystitis (infection or drug induced), urethritis or perineal irritation, urolithiasis, trauma, exercise, coagulopathies, and rarely bladder malignancies [12]. In certain communities in Africa and Asia, *Schistosomia hematobium* is an important cause of hematuria and proteinuria which may lead to lower urinary tract dysfunction and chronic kidney disease [13]. Exercise-induced hematuria is transient occurring after severe exercise and resolving within 48 h. Bleeding disorders such as hemophilia or thrombocytopenia can result in both microscopic and gross hematuria. Renal infarction presenting with gross hematuria can occur in children with sickle cell disease [14].

Of the nonglomerular causes, hypercalciuria is seen in 26–36% of children with gross or microscopic hematuria [15–17]. Hypercalciuria is associated with a strong family history of urolithiasis [18, 19], with a suggestion that this may have an autosomal dominant inheritance pattern [20]. The nutcracker syndrome is another cause of nonglomerular hematuria [21, 22] that appears more commonly in Asian communities. Hematuria occurs following compression of the left renal vein between the superior mesenteric artery and the aorta. In Japan and Korea, the ultrasonographic findings consistent with the nutcracker syndrome have been described in 30–45% of children with hematuria [23, 24]. These children are usually asthenic in habitus, and present with either microscopic or macroscopic hematuria, which may be associated with left flank pain and left varicocele in boys. Symptoms resolve in up to 75% of children over 24 months, following weight gain which is associated with an increase in retroperitoneal adipose tissue deposition resulting in a decrease in left renal vein hypertension [25, 26].

On the other hand, macroscopic hematuria which is glomerular in origin usually presents as dark red or cola-colored urine, often occurring together with upper respiratory tract symptoms (synpharyngitic). The child may have recurrent episodes of gross hematuria, and this is seen with many of the glomerulonephritis and familial hematuria syndromes that are progressive, in particular Alport syndrome. Postinfectious glomerulonephritis is still the most common etiology in children presenting with the full-blown symptoms of acute nephritis, that is, cola-colored urine, edema, and hypertension. However, the other systemic causes of glomerulonephritis in children must be considered, in particular IgA vasculitis (Henoch-Schönlein nephritis) and lupus nephritis.

Microscopic hematuria is often asymptomatic, with the most common causes being glomerulopathies in particular postinfectious glomerulonephritis, immunoglobulin A (IgA) nephropathy, and the familial hematuria syndromes as outlined in Table 2 [27]. Of the familial hematuria syndromes involving mutations in the α-chains of the collagen IV gene (*COL4A1* to *COL4A6*) (Table 2) [28], thin basement membrane nephropathy (TBMN), also known as benign familial hematuria, is the most common cause of persistent microscopic hematuria. It is now increasingly recognized that TBMN and Alport syndrome have a common molecular basis [29]. Alport syndrome (AS) is a progressive hematuric glomerulopathy associated with ultrastructural changes of the glomerular basement membrane, sensorineural deafness, and ocular abnormalities [29–33]. The X-linked form due to a *COL4A5* gene mutation is the most common form occurring in 85% of patients. Autosomal Alport syndrome due to biallelic (homozygous or compound heterozygous) mutations in *COL4A3* or *COL4A4* genes behaves in an autosomal recessive manner, and is associated with a 100% risk of progression to end-stage kidney disease, the timing of which is dependent on the genotype. Heterozygous mutations in *COL4A3* or *COL4A4* may exhibit a dominant form of inheritance and include those who have been diagnosed with TBMN. It is now recognized that TBMN is a spectrum of autosomal Alport syndrome, where the risk of progressive glomerulopathy is up to 20% in the presence of factors such as proteinuria, sensorineural deafness, family history of end-stage kidney disease and histological findings of focal segmental glomerulosclerosis, or glomerular basement membrane thickening and lamellation. Digenic Alport syndrome includes patients with mutations in two of the *COL4A3*, *COL4A4*, or *COL4A5* genes. Those with *COL4A3* and *COL4A4* mutations in the trans position on the alleles exhibit an autosomal recessive inheritance pattern, 100% of whom will have progressive glomerulopathy, whereas the same two mutations in the cis position exhibit an autosomal dominant inheritance pattern with up to 20% showing progression. Males with *COL4A5* and either *COL4A3* or *COL4A4* all progress to end-stage kidney failure.

Other genetic forms of glomerular hematuria include IgA nephropathy which is one of the most common glomerulopathies worldwide. In countries where IgA nephropathy is prevalent, 10 to 35% of children undergoing renal biopsy for isolated hematuria were found to have the disease [34, 35]. Children with IgA nephropathy present commonly either with recurrent gross hematuria associated with upper respiratory tract infections or with asymptomatic hematuria with or without proteinuria. Familial occurrence has been described in this genetically complex multifactorial disease [36, 37].

Another cause of familial hematuria is seen in the group of disorders known as C3

Table 2 Familial hematuria syndromes

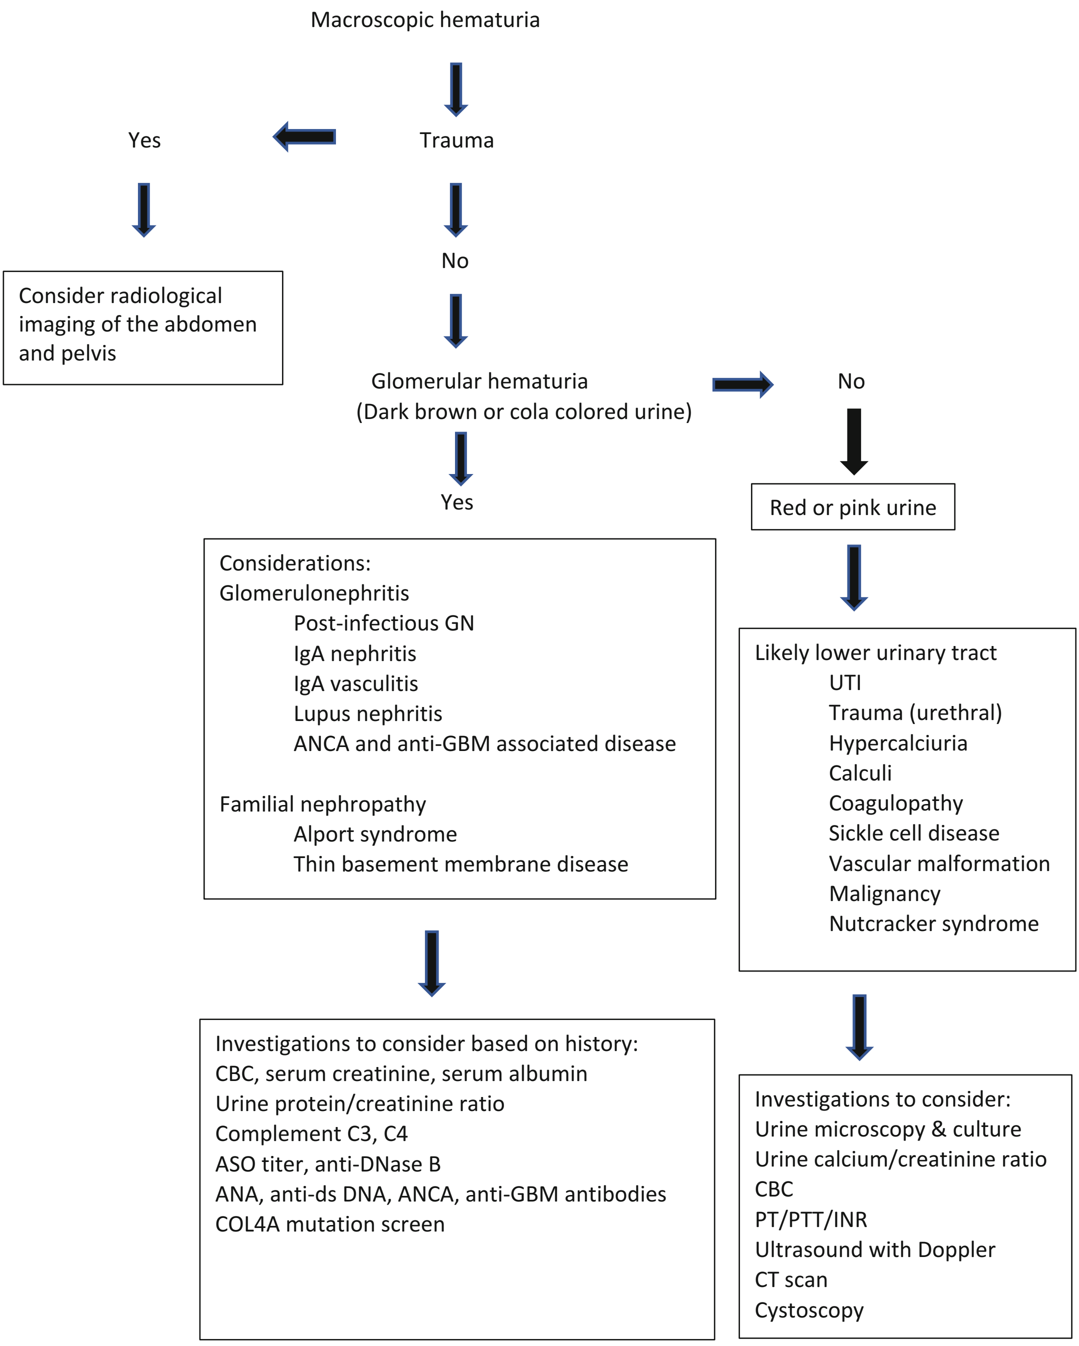
Inheritance	Gene(s)	Protein	Estimated risk of ESKD* (Median age)
X-linked Alport syndrome	*COL4A5* Hemizygous (male) Homozygous (female)	α5(IV)	100% (25 years) Up to 25% (49 years)
Autosomal Alport syndrome	*COL4A3* or *COL4A4* Recessive (homozygous or compound heterozygous) Dominant	α3(IV) or α4(IV)	100% (15 years) $<1\%$ if no risk factors (TBMN**); $\geq 20\%$ if risk factors present (60 years)
Digenic Alport syndrome	*COL4A3* and *COL4A4* Mutations in trans Mutations in cis Mutations in *COL4A5* and in *COL4A3* or *COL4A4*	α3(IV) and α4(IV)	Up to 100% Up to 20% Up to 100% (affected males)
Autosomal dominant macrothrombocytopathies	*MYH9* Heterozygous	Nonmuscle myosin heavy chain IIA	30% (15 years)
CFHR5 nephropathy	*CFHR5* Heterozygous (males) Heterozygous (females)	Complement factor H-related protein 5	80% (49 years) 20% (56 years)
Glomerulopathy associated with fibronectin deposition	*FN1*	Fibronectin 1	>90% (2nd to 6th decade)

*ESKD: End stage kidney disease
**TBMN: Thin basement membrane nephropathy

glomerulopathy, which is characterized by deposition of complement 3 (C3) without immunoglobulins, low serum C3 levels but normal C4 levels [38]. This comprises the clinical conditions known as dense deposit disease, C3 glomerulonephritis, and complement factor H-related 5 (CFHR5) nephropathy [38–40]. Mutations in *CFH*, *CFI*, *C3*, and *CFHR5* genes encode proteins that regulate the alternative complement pathway. Studies from families of Cypriot descent have shown that patients with duplication of exons 2–3 of the *CFHR5* gene present with hematuria, proteinuria, and hypertension, with up to 50% progressing to end-stage kidney failure within 10 years of diagnosis [40]. Another rare cause of familial hematuria is the autosomal dominant MYH9 (ADM9) spectrum disorders caused by mutations in the *MYH9* gene encoding for the nonmuscle myosin heavy chain IIA [41, 42]. Extrarenal symptoms include macrothombocytopenia, sensory hearing loss, congenital cataract, and leukocyte Döhle bodies in neutrophils. The associated nephropathy seen in 30–70% of patients presents initially with microscopic hematuria with proteinuria developing as the disease progresses, and finally reaching end-stage kidney failure in young adulthood. De novo *MYH9* gene mutations may occur in 35%. Fibronectin gene mutations also result in an autosomal dominant glomerulopathy associated with fibronectin deposits [43, 44]. Clinical features include microscopic hematuria, proteinuria, and hypertension with progression to end-stage kidney disease by the second to sixth decade of life [45].

Clinical Approach (Figs. 1 and 2)

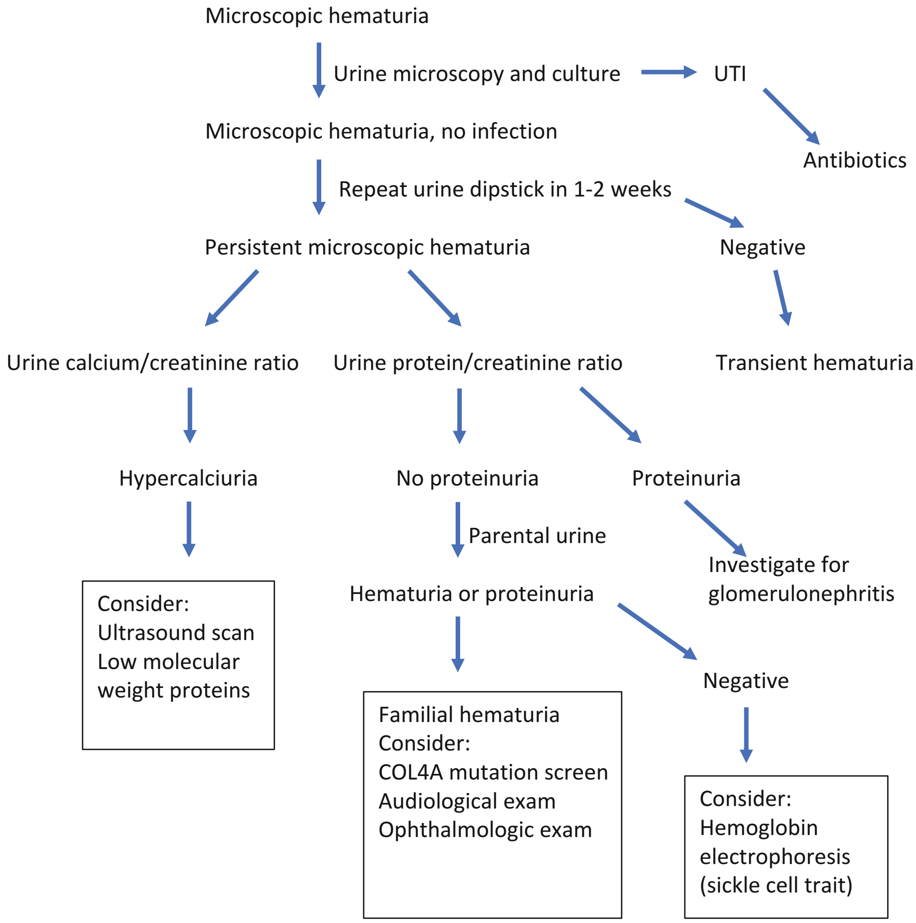
A comprehensive history will help in elucidating the cause of the hematuria. Points to ask in the history include the color of the urine, timing of color change in relation to urinary stream, and associated signs, symptoms, illness, or activity. In girls at the peripubertal age, menarche as a cause of hematuria should be considered. Transient hematuria has been found in association with fever, exercise, urinary tract infections (which usually also present with dysuria and pyuria),



Macroscopic hematuria
Trauma
Yes
Consider radiological imaging of the abdomen and pelvis
No
Glomerular hematuria (Dark brown or cola colored urine)
Yes
No
Red or pink urine
Considerations:
Glomerulonephritis
Post-infectious GN
IgA nephritis
IgA vasculitis
Lupus nephritis
ANCA and anti-GBM associated disease
Familial nephropathy
Alport syndrome
Thin basement membrane disease
Likely lower urinary tract
UTI
Trauma (urethral)
Hypercalciuria
Calculi
Coagulopathy
Sickle cell disease
Vascular malformation
Malignancy
Nutcracker syndrome
Investigations to consider based on history:
CBC, serum creatinine, serum albumin
Urine protein/creatinine ratio
Complement C3, C4
ASO titer, anti-DNase B
ANA, anti-ds DNA, ANCA, anti-GBM antibodies
COL4A mutation screen
Investigations to consider:
Urine microscopy & culture
Urine calcium/creatinine ratio
CBC
PT/PTT/INR
Ultrasound with Doppler
CT scan
Cystoscopy

Fig. 1 Flow chart of approach to macroscopic hematuria

and trauma. Lower urinary tract origin of hematuria is associated with passage of fresh blood with or without clots. Hematuria occurring at the beginning of the urinary stream is seen in urethral causes such as urethritis, whereas terminal hematuria is indicative of a bladder cause such as bladder calculus or tumors and schistosomiasis. This is usually accompanied by lower urinary tract symptoms such as frequency, urgency, and dysuria. In addition, a history of sexual activity



Microscopic hematuria
Urine microscopy and culture
UTI
Antibiotics
Microscopic hematuria, no infection

Consider: Hemoglobin electrophoresis (sickle cell trait)

Fig. 2 Algorithm for evaluation of microscopic hematuria

should be obtained in adolescents. The presence of flank pain or abdominal pain could suggest hydronephrosis, urolithiasis, nutcracker syndrome, or hemorrhage in polycystic kidney disease. Detection of ballotable kidneys and palpable bladder on examination will aid in the diagnostic evaluation.

Children with acute glomerulonephritis present with cola-colored or dark brown urine associated with edema and hypertension, accompanied by a latent history of upper respiratory tract infection 7 to 10 days or skin infection 2 to 3 weeks prior to onset of hematuria. Recurrent episodes of gross hematuria occur in many of the glomerulopathies, in particular IgA nephropathy and the other familial hematuria syndromes. Evaluation for extrarenal symptoms such as hearing loss and ocular abnormalities should be performed. Systemic signs to look for on physical examination include fever, pallor, bruising, rashes, joint swelling, mouth ulcers, hypertension, hepatosplenomegaly, and lymphadenopathy.

Evaluation of the family history not only of hematuria but in particular onset of end-stage kidney disease will often give a clue as to the underlying diagnosis. In addition to the familial hematuria syndromes, other conditions associated with a positive family history include stone disease and polycystic kidney disease.

The first step in the investigation is to determine the presence of hematuria. Urine dipstick examination has been used as a screening tool to detect hematuria. This test is based on the pseudoperoxidase activity of hemoglobin to catalyze the reaction between heme and tetramethylbenzidine resulting in a green-blue color due to the oxidized chromogen. These reagent strip tests are highly sensitive and can detect as low as five red blood cells per microliter or 150 microgram per liter of free hemoglobin. Causes of false positive results include hemoglobinuria, myoglobinuria, and presence of oxidizing agents in the urine such as vegetable peroxidases and microbial peroxidases associated with bacterial contamination of the urine [46]. Causes of false negative results include presence of large amounts of reducing agents such as ascorbic acid and high urine–specific gravity, which causes crenation of red blood cells preventing lysis.

Confirmation of hematuria by urine microscopic examination demonstrates the presence of red blood cells of more than 5 per microliter in a fresh uncentrifuged midstream urine specimen or more than 3 red blood cells per high-power field in the centrifuged sediment from 10 ml of freshly voided midstream urine [2]. False negative results can occur when the urine is of low specific gravity or is alkaline as this causes red blood cell lysis. The presence of red cell casts in fresh urine is indicative of a glomerulonephritis. These disintegrate in alkaline urine, appearing as granular casts. In children with asymptomatic microscopic hematuria, further evaluation is indicated if the hematuria is persistent, that is, present in two out of three consecutive samples.

The next step in evaluating the child with hematuria is to determine if this is due to glomerular or nonglomerular origin. The presence of greater than 30% dysmorphic red blood cells, in particular acanthocytes on urine phase contrast microscopy, is indicative of glomerular hematuria, whereas greater than 90% of isomorphic cells are seen in nonglomerular hematuria [47, 48]. Accompanying significant proteinuria of greater than 20 mg/mmol (0.2 g/g creatinine) in children older than 2 years of age and 50 mg/mmol (0.5 g/g creatinine) in younger children is also suggestive of an underlying glomerulopathy. Proteinuria may be detected in patients with macroscopic hematuria, but is usually less than 2+ (1 g/L) on dipstick examination.

In children with nonglomerular hematuria, urine culture should be sent especially if there are lower urinary tract symptoms or fever. Gross hematuria associated with lower urinary tract symptoms is suggestive of hemorrhagic cystitis, and urine should be sent for adenovirus culture. BK virus infection should also be considered in immunocompromised patients with cystitis. In endemic areas, the urine should be examined for *Schistosomia hematobium* ova.

As hypercalciuria is a common cause of nonglomerular hematuria, the spot urine calcium to creatinine ratio should be assessed. A value greater than 0.6 mmol/mmol (0.2 mg/mg creatinine) in children 2 years and older, and greater than 1.7 mmol/mmol (0.6 mg/mg creatinine) in infants between the ages of 6 and 12 months is indicative of hypercalciuria [49, 50]. If there is accompanying abdominal pain, in particular loin to groin pain suggestive of ureteric calculi, a plain abdominal radiograph is indicated. Ultrasound scan of the kidneys and bladder is indicated in nonglomerular hematuria to exclude congenital malformations including cystic kidney disease, renal calculi, and tumors.

Doppler ultrasound of the left renal vein is useful to exclude nutcracker syndrome in children with asthenic habitus or who have recurrent left flank pain associated with hematuria. Nutcracker syndrome is detected by Doppler ultrasonographic assessment of the left renal vein diameter and peak velocity. Suggested ultrasonographic criteria for diagnosis include an anteroposterior diameter ratio between the distended and narrowed portions of the left renal vein of greater than 4.0, and peak velocity ratio between the narrowed and distended portions of the left renal vein of greater than 4.2 [25, 51]. Axial imaging by computed tomography or magnetic resonance imaging may be required when Doppler renal vein ultrasonography is not diagnostic [25, 26]. The angle between the superior mesenteric artery and abdominal aorta should be less than 35° to diagnose nutcracker syndrome. Compression of the left renal vein in the fork between the superior mesenteric artery and abdominal aorta results in a left renal vein hilar to aortomesenteric diameter ratio of greater than 4.9 accompanied by gonadal vein distension and pelvic congestion. The “beak” sign is the most diagnostic on computed tomography imaging, and is due to severe narrowing of the left renal vein at the aortomesenteric portion [52].

Coagulation screen is necessary if there is a history suggestive of a bleeding disorder. Finally, cystoscopy is indicated in nonglomerular hematuria if a bladder or urethral pathology is suspected due to accompanying voiding symptoms, or when a mass is detected on bladder ultrasound, or to lateralize the source of bleeding.

In children with glomerular hematuria, renal function assessment in the form of blood urea and serum creatinine is required. Serum albumin should be measured if there is significant proteinuria. Subsequent investigations are tailored according to the type of clinical presentation. As the familial hematuria syndromes are an important cause of hematuria in children, urine screening of the family is useful. Audiometry to detect high-frequency sensorineural hearing loss and screening for ophthalmologic abnormalities may be indicated in patients with suspected Alport syndrome. If the rare MYH9 spectrum of disorders is suspected, a peripheral blood smear will be useful to look for macrothrombocytopenia and basophilic cytoplasmic leukocyte inclusion bodies (Döhle-like bodies). Genetic analysis for the relevant mutations associated with the familial hematuria syndromes is recommended in the presence of a positive family history or suggestive clinical, laboratory, or biopsy features.

Evaluation of children with suspected glomerular pathology should include serum complements C3 and C4, anti-streptolysin O titers (ASOT) or anti-DNAse B antibody, anti-nuclear antibodies (ANA), anti-double-stranded DNA (dsDNA) antibody, anti-neutrophil cytoplasmic antibodies (ANCA) in particular anti-proteinase 3 and anti-myeloperoxidase antibodies, IgA levels, hepatitis B surface antigen, and viral titers if appropriate. Kidney ultrasound is useful in the evaluation of a patient with glomerular hematuria to assess chronicity of the glomerulonephritis by determining kidney size and echogenicity.

Kidney biopsy is indicated in those with significant proteinuria (>1 g/1.73m^2/day) except in post-infectious glomerulonephritis, persistently low serum complement C3, unexplained kidney failure, family history of significant kidney disease suggestive of Alport syndrome where genetic analysis is not available, and recurrent gross hematuria of unknown etiology.

Approach to the Child with Proteinuria

Introduction

Proteinuria, like hematuria, is one of the most common reasons why a child is referred to a pediatric nephrologist. The presentation of a child with proteinuria can range from incidental detection of protein following urine dipstick testing during a routine medical visit in an asymptomatic child to presentation with generalized edema and nephrotic syndrome. The presence of glomerular proteinuria is often a sign of significant disease that needs further evaluation and treatment. However, there are a few situations in children where proteinuria can be transient or physiological such as during a febrile illness or following exercise.

Proteinuria is a general term which refers to increase loss of plasma proteins in the urine. This can be either due to: (1) increased glomerular permeability to large-molecular-weight proteins (for example albumin in glomerular diseases such as nephrotic syndrome), (2) incomplete tubular reabsorption of low-molecular-weight proteins (for example beta 2 microglobulin and retinol binding protein in renal tubular disorders such as cystinosis and Dent disease), and (3) increased plasma production of low-molecular-weight proteins (such as immunoglobulin-free light chains in monoclonal gammapathies and chronic inflammatory conditions).

Albuminuria Versus Proteinuria

Albuminuria refers to increased albumin excretion in the urine and has been increasingly used instead of proteinuria as a marker of chronic kidney disease in adults. The KDIGO (Kidney Disease: Improving Global Outcomes) 2012 clinical practice guideline for the evaluation and management of chronic kidney disease has incorporated albuminuria in the classification of chronic kidney disease in adults [53]. In health, <30% of the total protein in the urine is albumin, with Tamm–Horsfall protein (secreted by the ascending limb of loop of Henle) making up approximately 50% and the rest includes small quantities of immunoglobulins, transferrin and beta-2 globulin [54]. However, as protein losses increase albumin becomes the predominant protein in the urine [55]. In addition, urinary albumin measurement is technically superior to urine protein measurement. Some authors have, therefore, strongly recommended measuring albuminuria only for assessing chronic kidney disease [55, 56]. Although albuminuria appears to be increasingly adopted as an early marker of chronic kidney disease in adults, recent guidelines for children [57] recommend measuring proteinuria rather than albuminuria [53, 54, 58]. Although, one can miss the occasional child with tubular proteinuria when measuring albuminuria to detect proteinuria, urine total protein assessment is not a reliable marker for tubular proteins, and one should specifically measure urine low molecular proteins such as beta 2 microglobulin and retinol binding protein if renal tubular disease is suspected.

How to Measure Urine Protein

Urine dipstick: Urine reagent strip devices (dipsticks) are commonly used as a screening test for proteinuria. It is a semi-quantitative test where the test pad changes in color depending on the concentration of albumin in the urine [59]. The protein pad does not detect other proteins such as gamma globulins or Bence Jones proteins. The results are affected by the concentration and the pH of the urine. An alkaline or concentrated urine sample can lead to false positives and conversely acidic or dilute samples can result in false negatives. The dipstick will also be falsely negative when there is non-albumin proteinuria such as in renal tubular disorders. In general, 1+ protein on most dipstick is approximately 330–669 mg/l of protein (urine protein: creatinine ratio [urine PCR] 50-99 mg/mmol or 0.5–0.99 g/g), 2+ is 1000–2000 mg/l (100–450 mg/mmol or 1–4.5 g/g), and 3+ is >3000 mg/l (>450 mg/mmol or >4.5 g/g) [55]. A number of international guidelines do not recommend use of dipstick testing for detection of proteinuria because of the high false negative and poor negative predictive value compared to laboratory testing [55, 57]. Therefore, where accurate quantification of proteinuria is required, a urine sample should be sent to the laboratory for a timed collection measurement or for urine albumin:creatinine ratio (ACR) or PCR.

Spot Urine Sample Versus 24-h Collection

Although 24-h urine collection was previously the gold standard for assessment of proteinuria, this has largely been replaced by spot urine samples. A number of studies have shown that the spot urine protein (or albumin): creatinine ratio provides an accurate estimation of protein excretion rate [60]. It is also more convenient to obtain when compared to 24-h urine collection. Therefore, spot urine samples should be utilized to detect and monitor proteinuria in children [58].

Definition: The definition of proteinuria depends on the age of the child. Neonates have higher levels of protein in the urine, particularly in the first 2 weeks of life. In preterm infants this is significantly higher and predominantly composed of tubular proteins [61]. Beyond 6 months and up to 24 months urine PCR of <50 mg/mmol or 0.5 g/g is considered normal. In children over 2 years a urine PCR of <20 mg/mmol (0.2 g/g) is normal. If a 24 hour urine collection is performed, a protein excretion of <100 mg/m^2/24 h is normal [54]. Generally, nephrotic-range proteinuria is defined by a urine PCR > 200 mg/mmol (0.2 g/g) in a spot sample and in a timed or 24-h collection >40 mg/m^2/h or 3 g/1.73m^2/day. Microalbuminuria is defined by a urine ACR >3 mg/mmol (>0.3 g/g) in a first morning urine sample; the standard dipstick test does not detect this level of proteinuria.

Clinical Approach

Proteinuria is a relatively common problem. In a mass school screening program in Japan involving over 380,000 children aged 6–14 years, isolated proteinuria was detected in a first morning urine sample in 0.62% of children 6–11 years of age and 2.3% in 12–14 year age group [4]. However, upon repeat testing, the positive rates dropped to 0.08% in the younger group and 0.37% in the older age group. The study found that asymptomatic urinary abnormalities were 10 times more frequent than significant pathology in those children who had histological evaluation, demonstrating the unacceptably high sensitivity of mandatory urine screening program in asymptomatic school children.

Once proteinuria is detected on a dipstick test, it is important to establish if this is pathological or nonpathological proteinuria. Table 3 lists the causes of proteinuria.

Nonpathological Proteinuria

In many children, proteinuria is transient and is not present in all the urine samples tested. This may be related to an inter-current illness or posture. Repeating the test when the child has recovered from the illness or performing the test on a first morning sample helps clarify the situation. Children with intermittent or transient proteinuria do not require detailed investigations and there is no evidence to suggest that this has any prognostic significance.

(a) Febrile proteinuria: Proteinuria is often detected in children without underlying kidney disease during a febrile illness, usually where the temperature is >38.4 °C [62]. Resolution of proteinuria when the test is repeated following recovery from the acute illness supports the diagnosis. While no explanation is available for this phenomenon, it is likely that the state of hydration, plasma volume, and stress hormones such as adrenaline might have a role to play.

(b) Exercise-induced proteinuria: Proteinuria is well recognized after strenuous exercise. This can range from normal physiological excretion to up to 120 mg/hr. The type of physical activity appears to influence the amount of proteinuria, with subjects engaged

Table 3 Causes of proteinuria

A) Non-pathological proteinuria	B) Pathological proteinuria	
1. Febrile proteinuria 2. Exercise induced proteinuria 3. Orthostatic proteinuria	1. Glomerular proteinuria	2. Tubular proteinuria
	a) Primary glomerular disease Idiopathic childhood nephrotic syndrome Focal segemental glomerulosclerosis Mesangiocapillary glomerulonephritis Congenital nephrotic syndrome Membranous nephropathy	a) Inherited Cystinosis Lowe syndrome Galactosemia Mitochondrial cytopathies Dent disease Wilson disease Tyrosinaemia Hereditary fructose intolerance
	b) Secondary glomerular disease Post-infectious glomerulonephritis IgA vasculitis Lupus nephritis Alport syndrome Hepatitis B and C Human immunodeficiency virus Amyloidosis	b) Acquired Drug induced Pyelonephritis Acute tubular necrosis Heavy metal poisoning
	c) Other glomerular diseases Hemolytic uremic syndrome Hypertension Diabetes mellitus Hyperfiltration	

in maximal short-term running excreting more proteins when compared to swimming, bicycling, or rowing, despite engaging in similar intensity of exercise as demonstrated by post-exercise lactate levels [63]. The mechanism of exercise-induced proteinuria is thought to be renal vasoconstriction and consequently decreased glomerular filtration rate (GFR) along with increased glomerular permeability and impaired protein reabsorption [63]. A normal first morning urine PCR 48 hours after the intense exercise would help support the diagnosis of exercise-induced proteinuria. While evidence in children is lacking, data from adult studies do not suggest that this transient proteinuria is pathological.

(c) Orthostatic proteinuria: This is one of the most common causes of nonpathological proteinuria, with a prevalence of 0.65–5% reported in children on initial screening. The prevalence may be less if the first, second, and third random urine samples are checked at 2 weeks intervals following the initial detection of asymptomatic proteinuria as this method is more likely to exclude other causes of transient proteinuria [64]. Orthostatic proteinuria is more often seen in thin children compared to those who are overweight. The peak incidence is in adolescence and it is rare after the age of 30 years. The mechanism for orthostatic proteinuria has not been clearly defined. Since it is more commonly seen in children with low BMI and the prevalence reduces with increasing age and concomitant increase in adiposity, an exaggerated response to upright posture with or without anatomical factors such as renal vein entrapment has been postulated [64]. In those children with persistent proteinuria on a random sample, a first morning sample should be sent to measure urine PCR. A normal first morning urine PCR in a child with proteinuria on a random urine sample would confirm a diagnosis of orthostatic proteinuria. The long-term prognosis appears to be excellent with resolution of the proteinuria in the vast majority of affected patients during adulthood. Although some would recommend follow-up of these children, it does not seem justifiable in the absence of coexisting hematuria, hypertension, or impaired kidney function.

Pathological Proteinuria

Pathological proteinuria is most often glomerular in origin. The mechanism of proteinuria can vary depending upon the underlying pathology. For instance, in minimal change disease there is loss of negative charge in the glomerular filtration barrier, leading to selective albuminuria and very little increase in the glomerular permeability to globulins [65]. Mutations in the slit diaphragm proteins such as nephrin and podocin lead to absence or malfunction of the slit diaphragm, and consequently nonselective proteinuria [66]. In patients with reduced nephron mass such as children with scarred kidneys and in kidney donors there is increase in glomerular permeability to plasma proteins in the residual nephrons, leading to proteinuria. Another mechanism is due to changes in glomerular capillary pressure secondary to disease such as hyperfiltration in diabetic nephropathy, resulting in increased filtration fraction.

Tubular proteinuria is most often due to inherited or acquired damage to the proximal convoluted tubule. The predominant proteins in the urine in this instance are low-molecular-weight proteins such as β2 microglobulin and retinol-binding protein rather than albumin. The degree of proteinuria is usually <1 g/1.73m^2/day. Secretory proteinuria is seen in neonates due to excretion of Tamm–Horsefall protein. Monoclonal gammopathy or multiple myeloma can lead to overflow proteinuria due to increased production which can exceed the maximal tubular reabsorption for that protein.

Child presenting with persistent proteinuria: Nephrotic-range proteinuria and nephrotic syndrome are dealt with in a separate chapter and so will not be discussed here. We will discuss the evaluation of child with subnephrotic-range proteinuria – urine PCR 50-200 mg/mmol (0.5–2.0 g/g) in a spot sample or <40 mg/m^2/h (<3 g/1.73m^2/day) in a timed collection.

History: It is important to ask about any recent illness and inquire about fluid intake and urine output. Document any history of visible blood in the urine. Ask about any facial or lower limb swelling. Connective tissue disorder symptoms such as rash, joint pain, or swelling should be noted. Documentation of any drug intake, including nonsteroidal anti-inflammatory agents and antibiotics, is essential. Family history of connective tissue disease, deafness, or CKD should be obtained.

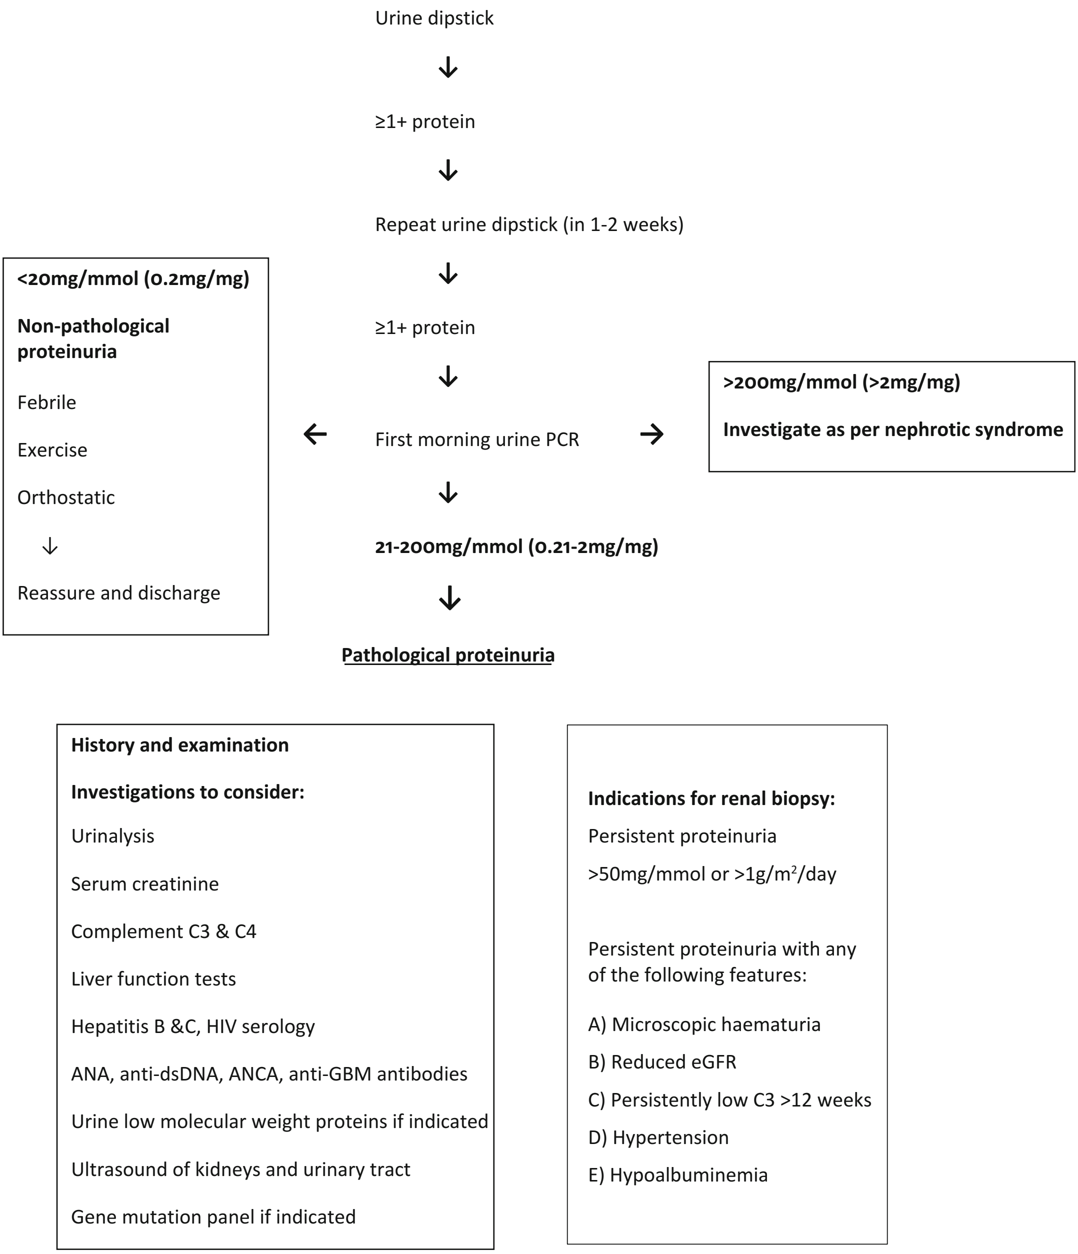
Physical examination: The general health of the child as to whether he/she is well or not should be noted. Blood pressure should be measured. Look for any dysmorphic features such as microcoria (Pierson syndrome) or ambiguous genitalia (Denys-Drash syndrome). Hypotonia is a feature of Galloway Mowat syndrome and also Pierson syndrome. Assess the peripheral circulation by checking the capillary refill time and also noting whether the hands and feet are warm or cool. Inspect for any vasculitic rash and joint swelling (IgA vasculitis and lupus nephritis). Examine for the presence of ankle edema, genital swelling, ascites, and pleural effusion. It is important to assess for signs of fluid overload such as raised jugular venous pulse, hepatomegaly, and gallop rhythm.

Investigations (Fig. 3): Detailed investigations are only indicated once persistent proteinuria has been confirmed. Therefore, the first step in the evaluation of a child referred with proteinuria is to establish if this is persistent or not. In those children found to have + or ++ of protein on dipstick test during an acute illness, repeating the test a couple of weeks following the illness will ensure that children with transient proteinuria are not unnecessarily investigated. Those children with persistent proteinuria of 1+ or more should have a first morning urine sample sent for urine PCR. If the result is >20 mg/mmol (>0.2 mg/mg), further evaluation is indicated. Requesting first morning urine PCR (ideally on 3 consecutive days) will also identify those children with orthostatic proteinuria.

Urine investigations: Dipstick analysis of the urine provides valuable information including the presence or not of blood, white cells, and nitrites. It also provides information about the specific gravity and pH of the urine. Urine microscopy and culture is important in all children presenting with proteinuria to look for the presence of hematuria, pyuria, casts, and crystals. It also helps identify any undiagnosed urinary tract infection. Urine tubular proteins such as β2 microglobulin and retinol binding protein should be requested if a tubular disorder is suspected.

Blood investigations: Assessment of kidney function by measuring plasma creatinine along with urea and electrolytes is recommended. The Schwartz formula [67] should be utilized to calculate the estimated GFR. A reduced eGFR is an indication for performing a kidney biopsy. Measuring plasma albumin along with liver function tests is important as this will show if the proteinuria has led to drop in the plasma levels of albumin. It usually takes more than a few days of nephrotic-range proteinuria for the plasma albumin to drop to <30 g/l. In a child with proteinuria with or without hematuria, a low plasma albumin is an indication to perform a kidney biopsy. A lipid profile is often checked in children with nephrotic syndrome as it will be raised. However, there is no indication to treat this in the acute phase.

Complement C3 and C4 should be checked in all children with persistent proteinuria without an obvious cause. Post-infectious glomerulonephritis, shunt nephritis, and C3 glomerulopathy are associated with low C3 while low C3 and C4 are seen in lupus nephritis. Antinuclear antibodies (ANA), anti-double-stranded DNA antibodies (dsDNA), anti-streptolysin O titers (ASOT) or anti-DNase B titers, and anti-neutrophil cytoplasmic antibodies (ANCA) ought to be requested if there are any indication of glomerulonephritis. In certain children where the history and the initial investigations are suggestive of a chronic illness, human immunodeficiency virus (HIV) and hepatitis B and C virus screen may be indicated. In addition, a blood sample may be indicated for gene mutational studies, particularly if inherited cause of proteinuria is suspected based on the family history or clinical examination.



Urine dipstick
≥1+ protein
Repeat urine dipstick (in 1-2 weeks)
≥1+ protein
First morning urine PCR
<20mg/mmol (0.2mg/mg)
Non-pathological proteinuria
Febrile
Exercise
Orthostatic
Reassure and discharge
>200mg/mmol (>2mg/mg)
Investigate as per nephrotic syndrome
21-200mg/mmol (0.21-2mg/mg)
Pathological proteinuria
History and examination
Investigations to consider:
Urinalysis
Serum creatinine
Complement C3 & C4
Liver function tests
Hepatitis B &C, HIV serology
ANA, anti-dsDNA, ANCA, anti-GBM antibodies
Urine low molecular weight proteins if indicated
Ultrasound of kidneys and urinary tract
Gene mutation panel if indicated
Indications for renal biopsy:
Persistent proteinuria
>50mg/mmol or >1g/m²/day
Persistent proteinuria with any of the following features:
A) Microscopic haematuria
B) Reduced eGFR
C) Persistently low C3 >12 weeks
D) Hypertension
E) Hypoalbuminemia

Fig. 3 Algorithm for evaluation of child with proteinuria

Imaging investigations: Ultrasonography of the kidneys is routinely performed in the evaluation of most children with proteinuria in order to exclude any structural abnormalities such as small kidneys due to loss of nephron mass, which can be congenital or acquired. Nuclear medicine scans are useful in identifying scarring in the kidneys where proteinuria due to hyperfiltration is suspected. Doppler ultrasound is suggested for identifying renal artery stenosis; however, CT/MR angiogram and often digital subtraction angiography is required to diagnose these conditions.

Indications for Kidney Biopsy in a Child with Proteinuria (Fig. 3)

Persistent proteinuria: A kidney biopsy should be considered in any child with urine PCR >50 mg/mmol or 0.5 g/g (>1 g/1.73m^2/day) for more than 4 weeks. The presence of hematuria along with proteinuria also greatly increases the chance that a biopsy will lead to a diagnosis. A study from Korea found that IgA nephritis was the most common diagnosis made in children with combined proteinuria and hematuria initially identified through population screening [5]. A reduced eGFR is another indication for kidney biopsy. Post-infectious glomerulonephritis is an exception to this rule, as in the overwhelming majority of children with this condition there is spontaneous recovery of kidney function in a few weeks. A persistently low complement C3 level beyond 3 months is another indication for kidney biopsy as this often suggests immune complex or C3 glomerulopathy. Persistent proteinuria in a systemic condition such as lupus nephritis or IgA vasculitis merits a biopsy to help stage the condition and plan treatment.

Management of children with mild proteinuria: It is well recognized that glomerular proteinuria may play a role in progression of CKD. Proteinuria has also been linked to be a risk factor for cardiovascular diseases in adults. High levels of proteinuria can lead to complications such as hyperlipidemia, infection, and thromboembolism. It is therefore important that proteinuria is detected and where possible, specific treatment should be promptly instituted.

In those children where the urine PCR is between 20–50 mg/mmol or 0.2–0.5 g/g (300–1000 mg/1.73m^2/day) and the rest of the investigations have not identified a pathology, it is debatable whether to proceed to a kidney biopsy as the chances of identifying a progressive disease is small and also because this may not alter the clinical management of the child. It is recommended that these children have 6–12 monthly assessment of proteinuria, blood pressure, and plasma creatinine. While reduction of proteinuria using angiotensin converting enzyme inhibitors (ACEi) has been shown to reduce the progression of chronic kidney disease in children [68, 69], there are no such data to support this treatment in those without chronic kidney disease. There is also the concern that progressive disease might be masked by treating with an anti-proteinuric medication before a diagnosis has been established. In view of this, regular monitoring of the clinical situation is indicated and proceeding to a kidney biopsy if there are any signs of disease progression. Following this, ACEi treatment can be considered for persistent proteinuria even in situations where a clear diagnosis has not yet been established. Tubular proteinuria is not thought to have a prognostic significance. The role of ACEi in reducing tubular proteinuria and protecting kidney function has not been established.

Abstract

Nephrotic syndrome is defined by massive proteinuria, hypoalbuminemia, edema, and hyperlipidemia. Proteinuria is secondary to a defect of the glomerular filtration barrier. The main complications of nephrotic syndrome are infections and thromboembolic events. Although nephrotic syndrome may be secondary to many renal diseases, idiopathic nephrotic syndrome is the most frequent cause in childhood with a complete remission following corticosteroid therapy in 90% of cases. Less frequently, nephrotic syndrome is due to a primary or secondary glomerulonephritis or to a genetic defect of podocyte or glomerular basement membrane proteins. Genetic testing is proposed in children with steroid-resistant idiopathic nephrotic syndrome, children less than 1 year, children with familial history of proteinuria, or those with extrarenal symptoms. Kidney biopsy is performed in children older than 12 years and children who do not respond to steroid therapy.

Keywords

Nephrotic syndrome · Minimal change disease · Focal segmental glomerulosclerosis · Genetic testing · Kidney biopsy

Definition

Nephrotic syndrome is defined by the presence of massive proteinuria (>50 mg/kg/day or >40 mg/hour/m^2 or urine protein/creatinine ratio >200 mg/

mmol), hypoalbuminemia (<30 g/l), peripheral edema, and hyperlipidemia.

The presence of edema is inconstant and does not always correlate with the serum albumin concentration. As fluid retention is primarily due to increased sodium reabsorption at the level of the collecting duct by the epithelial sodium channel (ENaC) [1], poor salt intake, for example, may explain the absence of edema. Urinary protein excretion may fall in patients with severe nephrotic syndrome when plasma albumin is very low.

Pathogenesis

Proteinuria in nephrotic syndrome is due to an increased filtration of macromolecules across the glomerular capillary wall. The glomerular filtration barrier is composed of three components: fenestrated endothelial cells, the glomerular basement membrane (GBM), and podocytes. The structure of the GBM comprises a central electron-dense layer, the lamina densa, an electron-lucent lamina rara interna on the endothelial cell side, and a lamina rara externa on the podocyte side [2]. The GBM is composed of type IV collagen, laminin, nidogen, and heparan sulfate proteoglycans, such as agrin [3]. Podocytes are highly specialized epithelial cells in contact with lamina rara externa through the foot processes [4]. Foot processes of adjacent podocytes interdigitate with 30–40 nm gaps that are maintained by the slit diaphragm, a zipper-like pattern membrane.

The filtration of macromolecules across the glomerular capillary wall is normally restricted by two mechanisms: charge-selectivity and size-selectivity [5, 6]. The endothelial cells and the GBM have a net negative charge due to polyanions such as heparan sulfate proteoglycans. This creates a charge barrier to filtration of large anions such as albumin. In minimal change disease, the most common cause of nephrotic syndrome in children, there is a loss of anionic charge that is not accompanied by any structural damage or change to the glomerular filtration unit observed by light microscopy [7]. However, electron microscopy demonstrates epithelial foot process effacement.

The glomerular capillary wall is size-selective, having functional pores of approximate radius of 40–45 A (radius of albumin is ~36 A) [6]. These pores appear to be located throughout the GBM and across the GBM at the slit diaphragms between adjacent epithelial cell foot processes. In comparison, the width of the endothelial cell fenestrae is much larger (375–400 A). As a result, the endothelial cell is not part of the size barrier to macromolecule filtration. In glomerular diseases other than minimal change disease, structural injury seen by light microscopy results in increase in the number of large pores in the GBM. This structural damage allows movement of normally restricted proteins of varying sizes (including large neutral proteins, such as IgG) across the filtration barrier.

Several mechanisms may lead to a glomerular injury and the nephrotic syndrome. In minimal change disease and idiopathic focal segmental glomerulosclerosis (FSGS), circulating factors alter podocyte function leading to proteinuria [8, 9]. Such circulating factors explain the immediate recurrence of proteinuria after kidney transplantation in patients who have progressed to end-stage renal disease. Immune mechanisms explain structural changes of the GBM secondary to in situ formation of immune complexes as in membranous nephropathy [10], in situ deposition of immune complexes as in lupus nephritis [11], and direct effects of anti-GBM antibodies as in anti-GBM disease [12]. Third, mutations of podocyte or slit diaphragm proteins leading to structural or functional defects of podocytes are observed in inherited forms of congenital syndrome, in ~30% of patients with steroid-resistant idiopathic nephrotic syndrome, and in some syndromic forms of nephrotic syndrome [13].

Clinical Evaluation at Onset

Clinical and laboratory evaluation are used to confirm the diagnosis and determine the underlying cause. The child should be examined to detect peripheral edema, ascites, or pleural or pericardial effusion. Blood pressure should be measured as hypotension may be related to hypovolemia, whereas hypertension may be related to glomerulonephritis. Physical examination is important to detect infection or thrombosis as a complication of the nephrotic syndrome.

The diagnosis of nephrotic syndrome is confirmed by the presence of both nephrotic-range proteinuria and hypoalbuminemia. Nephrotic-range proteinuria is defined as urine protein excretion greater than 50 mg/kg per day or 40 mg/m^2 per hour. It is higher at onset and decreases as plasma albumin concentration falls. However, it is difficult to obtain accurately timed urine collections in young children. An alternative method of quantitative assessment of urine protein excretion is measurement of the total protein/creatinine ratio on a spot urine sample. The ratio that is indicative of nephrotic-range proteinuria is greater than 2 mg protein/mg creatinine (200 mg protein/mmol creatinine).

Plasma protein levels are reduced, less than 50 g/l, due to hypoalbuminemia. Albumin level is lower than 30 g/l and may be less than 10 g/l. Electrophoresis shows low albumin and increased alpha 2-globulins and beta-globulins; the level of gamma-globulins depends on the cause of the nephrotic syndrome. For example, IgG levels are markedly reduced in minimal change disease and elevated in systemic lupus erythematosus.

Total cholesterol and LDL cholesterol are elevated, while HDL cholesterol is unchanged or low, particularly HDL2, leading to an increased LDL/HDL cholesterol ratio [14]. Patients with severe hypoalbuminemia have increased triglycerides and VLDL. Apoproteins, apo B, apo CII, and apo CIII, are also elevated. Levels of lipoprotein Lp(a) are elevated and further contribute to an increased risk of cardiovascular and thrombotic complications [15].

Serum sodium is often reduced due in part to hyperlipidemia and in part to dilution from renal retention of water due to hypovolemia and inappropriate antidiuretic hormone secretion. Hyperkalemia may be observed in cases of renal insufficiency. Hypocalcemia is related to hypoalbuminemia, and the level of ionized calcium is usually normal. Hemoglobin levels and hematocrit are increased in patients with plasma volume contraction. Thrombocytosis is common and may reach 5 x 10^8/l or 10^9/l. Fibrinogen and factors V, VII, VIII, and X are increased, whereas antithrombin III, the heparin cofactor, and factors XI and XII are decreased. These abnormalities contribute to a hypercoagulable state.

Patients with nephrotic syndrome should be examined for complications, such as bacterial infections (peritonitis, cellulitis) or thromboembolic events (pulmonary embolism; deep vein, cerebral venous, or renal vein thrombosis) [16, 17]. Despite the increase in extracellular fluid volume, some patients, particularly those with minimal change disease, present with features of decreased circulating volume (abdominal pain, tachycardia, peripheral vasoconstriction, oliguria, and decreased glomerular filtration rate). This is more frequent at onset of nephrotic syndrome or during a relapse [18].

The age at onset of the nephrotic syndrome is predictive of the cause. A nephrotic syndrome occurring during the first 3 months of life (congenital nephrotic syndrome) has most often a genetic cause [19, 20]. The clinical evaluation includes the search for extrarenal symptoms: pseudohermaphroditism, Wilm's tumor observed in children with the Denys-Drash syndrome, ocular malformations (microcoria, abnormal lens with cataracts, and retinal abnormalities) observed in Pierson syndrome, microcephaly, mental retardation, hiatus hernia in Galloway syndrome, nail anomalies, patellar aplasia, or hypoplasia in Nail-Patella syndrome. A nephrotic syndrome starting between 3 and 10 years is most often due to minimal change disease. In older children, other causes are more frequent such as idiopathic FSGS, membranous nephropathy, or IgA nephropathy. In this age group, secondary causes such as systemic lupus erythematosus are also more frequent.

Family history may show another family member affected with nephrotic syndrome or another renal disease and/or parental consanguinity suggesting a genetic form of the illness [21].

Clinical features are predictive of the most common form of nephrotic syndrome, minimal change disease [22, 23]. Minimal change disease represents more than 90% of nephrotic syndrome observed between 1 and 10 years of age. Such diagnosis is likely in patients younger than 10 years, with no syndromic features or family history, in absence of hypertension and hematuria, normal kidney function, and normal blood level of complement. As more than 90% of these patients are steroid responsive, an initial trial of steroid therapy is administered without further investigations.

Some patients with nephrotic syndrome present with additional nephritic features (macroscopic hematuria, hypertension, decreased renal function), suggesting primary (postinfectious glomerulonephritis) or secondary glomerulonephritis. The presence of extrarenal symptoms such as a cutaneous rash, joint pain, and lymphadenopathy favor a secondary form of the illness. Patients with a clinical presentation not suggestive of minimal change should be evaluated with additional investigations according to the clinical features (Table 1).

Estimation of urinary protein
Urinalysis to detect hematuria
Blood tests Complete blood count Total protein, albumin Urea, creatinine, estimated glomerular filtration rate Electrolytes: sodium, potassium, ionized calcium Lipids: LDL and HDL cholesterol, triglycerides Coagulation tests (prothrombin time, fibrinogen, ATIII)
Check for causes other than minimal change disease Complement levels (CH50, C3, C4) Antistreptolysin O Antinuclear antibodies, anti-double-stranded DNA; antineutrophil cytoplasmic antibodies Anti-glomerular basement antibodies Anti-PLA2R autoantibodies Serology for hepatitis B and C; Epstein-Barr virus, and human immunodeficiency virus
Renal ultrasound (kidney size, echogenicity)
Genetic screening: extended gene panel, whole exome sequencing
Kidney biopsy (light microscopy, immunofluorescence); electron microscopy (if necessary)

Indications for Genetic Testing

Genetic testing, if available, should be performed in children with primary steroid-resistant nephrotic syndrome, particularly those with familial history of proteinuria and with extrarenal symptoms [24, 25]. Whole exome sequencing technology detect a monogenic disease in 10–30% of cases, the most frequent being *NPHS2*, *WT1*, and *NPHS1* mutations [26]. Identification of pathogenic or likely pathogenic variations in these genes has important clinical implications [27, 28]. For example, immunosuppressive treatment is ineffective and should be withdrawn, and these patients have a low risk of recurrence after renal transplantation. Genetic testing is not recommended for children who respond to steroid therapy with complete remission of proteinuria. Genetic testing is also recommended in patients with congenital or infantile forms of nephrotic syndrome starting before 1 year of age.

Indications for Kidney Biopsy

A biopsy is performed in children presenting with a nephrotic syndrome beyond the age of 12 years, since the proportion of patients with minimal change disease decreases significantly thereafter, and side effects of steroid therapy are more important during puberty. A biopsy is required for children who fail to respond to steroid therapy in order to detect the underlying pathology. In patients with idiopathic steroid-resistant nephrotic syndrome, a kidney biopsy is important before starting treatment with calcineurin inhibitors. A biopsy is indicated when there is suspicion of renal pathology, other than minimal change. This is the case of children with macroscopic hematuria, hypertension, decreased renal function, or low complement level. In these patients, renal biopsy may show membranoproliferative glomerulonephritis, membranous nephropathy, IgA nephropathy, or C3 glomerulopathy (Table 2) [29].

Table 2 Causes of childhood nephrotic syndrome

Idiopathic nephrotic syndrome
Minimal change disease
Primary focal segmental glomerulosclerosis (FSGS)
Genetic diseases
Finnish type congenital nephrotic syndrome (*NPHS1*)
Autosomal recessive steroid-resistant NS (*NPHS2*)
Diffuse mesangial sclerosis (*WT1*, *PLCE1*, *LAMB2*, *NPHS2*)
Denys-Drash syndrome (*WT1*)
Frasier syndrome (*WT1*)
Pierson syndrome (*LAMB2*)
Galloway-Mowat syndrome (*WDR73*, *LAGE3*)
Charcot-Marie-Tooth disease (*INF2*)
Schimke immuno-osseous dysplasia (*SMARCAL1*)
Mitochondrial cytopathies
Alport syndrome (*COL4A5*, *COL4A4*, *COL4A3*)
Fabry disease (*GLA*)
α-1 antitrypsin deficiency (*SERPINA1*)
Infections
Post-streptococcal glomerulonephritis; other bacterial infections (endocarditis, visceral abscess, shunt nephritis); congenital syphilis
Parasitic infections (*Schistosoma mansoni*, *Plasmodium falciparum*, *Toxoplasma gondii*)
Human immunodeficiency virus, cytomegalovirus, polyomavirus, parvovirus B19
Hepatitis B, C
Drugs, toxins
Nonsteroidal anti-inflammatory drugs; gold; heroin; interferon; lithium; mercury; pamidronate; penicillamine; trimethadione
Malignancies
Hodgkin disease, non-Hodgkin lymphoma
Primary glomerulonephritis
Membranous nephropathy
Immune complex membranoproliferative glomerulonephritis
C3 glomerulopathy
IgA nephropathy
Crescentic glomerulonephritis: idiopathic, anti-glomerular basement membrane disease
Secondary glomerulonephritis
Henoch-Schonlein syndrome
Systemic lupus erythematosus
Microscopic polyangiitis; granulomatosis with polyangiitis; Churg-Strauss syndrome
Cryoglobulinemia
Others
Thrombotic microangiopathy; sickle cell disease; diabetes mellitus; amyloidosis; reduced renal mass (oligomeganephronia, renal hypodysplasia); obesity

Abstract

Steroid-resistant nephrotic syndrome (SRNS) is a leading cause of end-stage kidney disease in children. Recent findings from genomic studies suggests that 10–30% of all cases of SRNS are monogenic disease where mutation in a single gene is enough to cause disease. More than 60 single gene causes of SRNS have been reported and virtually all these genes localized to the podocyte the glomerular visceral epithelial cell of the kidney hence the term "podocytopathy." The mechanisms by which the mutations in these genes will cause disease is not completely known; however, emerging data showed that some of these genetic defects can disrupt the podocyte F-actin cytoskeleton and the slit diaphragm (SD), signalling at the SD, and also unsettle metabolic activities that are vital for the normal function of the podocyte. Findings from genomic studies is also informing better classification of disease, thus rather than relying on taxonomy that depends on therapy response and nonspecific findings on biopsy, childhood nephrotic syndrome can now be stratified into monogenic NS and immune-based NS. A subset of the latter is readily identifiable as circulating factor disease. This clearly defined disease stratification has implications for approach to therapy and prognostication. Future challenges include developing platforms for the utilization of genetic information in clinical decision process and harnessing multi-omics data and other cutting edge molecular platforms to identify new and specific treatment modalities for nephrotic syndrome.

Introduction

Gene discovery efforts aimed at unravelling the causes of Mendelian forms of nephrotic syndrome have resulted in the identification of pathogenic variants in a number of genes that encode proteins crucial for the establishment and maintenance of the glomerular filtration barrier. These discoveries have helped decipher the pathophysiologic mechanisms of the glomerular filtration process by revealing that most of the products of the defective genes are essential for glomerular podocyte function. Before the era of high-throughput genomics, the glomerular basement membrane was thought to be the crucial element of the filtration barrier and its constituents seemed to be good candidates to explain the pathogenesis of familial glomerulopathies. *COL4A* genes implicated in Alport syndrome were discovered almost a decade before the identification of *NPHS1* and *NPHS2* encoding nephrin and podocin, respectively, the key proteins necessary for proper podocyte function.

The discovery of *NPHS1* and later *NPHS2* was the turning point in the glomerulopathy research, and by the year 2000, molecular basis of hereditary nephrotic syndrome started to be resolved. A new category of diseases now named "podocytopathies" was established. Since then, the completion of human genome sequencing and advent of next-generation gene sequencing has greatly accelerated the discovery of new causative disease genes. Subsequently, dozens of genes crucial for podocyte functions were discovered revealing a picture of tremendous genetic heterogeneity for the phenotypically uniform disease. At present, there are 22 entities enlisted in the phenotypic series "nephrotic syndrome" (PS256300) in the Online Mendelian Inheritance in Man (OMIM) Database comprising all known human Mendelian disorders. Another 10 genes are listed in the "focal segmental glomerulosclerosis" (FSGS) phenotypic series (PS603278).

Overall, causative mutations in more than 60 genes have been identified, comprising genes which are selectively or preferentially expressed in the podocyte and encode for protein components of the slit diaphragm (SD), the cytoskeleton, the membrane protein complex linking these structures and intracellular cell signalling. Genetic abnormalities have been identified unexpectedly in cellular structures and pathways hitherto unknown to be involved in the pathophysiology of the disease including mitochondrial energy supply, the nuclear pore complex, and nuclear transcription factors. In recent years, the application of comprehensive genetic testing as the first-line diagnostic tool allowed also for identification of overlapping phenotypes with other hereditary nephropathies such as Dent disease, *DGKE*-associated disease, *TTC21B*-related nephronophthisis, or *PAX2*-related disorders. The list of genes mutated in syndromic and non-syndromic forms of steroid-resistant nephrotic syndrome (SRNS) is constantly evolving and comprises all types of Mendelian inheritance: autosomal recessive, autosomal dominant, X linked, and mitochondrial inheritance (Table 1, Fig. 1).

There is significant variability across the globe with respect to the most common underlying genetic defect in patients with nephrotic syndrome [1]. Although, there are few studies from sub-Saharan Africa and south-eastern Asia, a number of founder mutations have been identified in different geographic regions and populations (Fig. 2). Worldwide, *NPHS2* gene defect is considered the most common cause of hereditary nephrotic syndrome; however, not all ethnic groups share the same frequency of mutations in this gene; for example, in Chinese children and young adults, mutations in *NPHS2* is surpassed by mutations in *COQ8B* gene [2]. Distribution of pathogenic variants reflects geographical isolation, historical migrations, and reproduction in highly consanguineous communities leading to increased frequency of an allele originating from a historical founder effect or a recent bottleneck event in a given population. In general, these refer to a mutation inherited in autosomal recessive manner such as the classic Fin-major and Fin-minor variants in *NPHS1* that is exceptionally prevalent in Finland which was the rationale for the term "Finnish-type nephrotic syndrome" as the name for congenital nephrotic syndrome due to a *NPHS1* defect [3]. The other examples are: c.413G > A (p.Arg138Gln) and c.851C > T (p.Ala284Val) in *NPHS2* prevalent in Western Europe and Hispanic Americans, respectively [4]. The change c.2542G > T (p.Glu848*) in *SMARCAL1* is found frequently in populations of the Central/ Eastern Europe while the c.1339dupG in *COQ8B* reported in Kurdish families is a founder mutation originating from a region in southeast Turkey and c.2492A > C in *NUP107* in East Asians [5–7]. On the other hand, for genes inherited in autosomal dominant manner no founder effect has been reported so far. There are, however, a few recurrent mutation *hotspots* such as *WT1* p.Arg467Trp and c.1447 + 5G > A (previously referred to as p. R394W and IVS9 + 5 G > A respectively), *LMX1B* p.Arg426Gln or *TRPC6* p.Arg895Cys.

Genetic abnormalities, as well as immunological, toxic, infectious, metabolic, hemodynamic, and other mechanisms can alter the podocyte structure and function. Depending on the stage of development and associated environmental factors, podocyte alterations can lead to a wide spectrum of clinical syndromes that should be understood as a continuum and not as separate entities. Indeed, whether the podocytopathies are hereditary or acquired, isolated or syndromic, the molecular perturbations involved in the appearance and progression of renal lesions are closely intertwined. Additional evidence for SRNS/FSGS being a podocytopathy include data from humans and experimental studies that have shown that relative or absolute podocyte depletion or changes in its functional integrity is central to the initiation and progression of the lesion seen in FSGS [8–9]. Wiggins and his group demonstrated the quantitative relationship between podocyte number and evolution of FSGS in a rat model of diphtheria toxin-induced podocyte depletion in which the degree of podocyte loss is regulated. In this model, loss of 30–50% of podocytes seems to be the trigger for progressive kidney damage [9].

Mendelian podocytopathies share the common features of ultrastructural abnormalities of the podocyte foot processes and loss of integrity of

Table 1 Major single gene causes of nephrotic syndrome

Gene	Inheritance	Protein	Function
Slit diaphragm genes			
NPHS1	AR	Nephrin	Signalling between slit diaphragm and actin cytoskeleton
NPHS2	AR	Podocin	Interact with nephrin, link plasma membrane to F-actin cytoskeleton; mechanosensation
CD2AP	AR, AD	CD2 associated protein	Anchors slit diaphragm to actin cytoskeleton
TRPC6	AD	Transient receptor potential channel 6	Regulates calcium homeostasis and chemo/mechanosensation
PLCE1	AR	Phospholipase epsilon1	Modulates slit diaphragm signalling through calcium regulation
FAT1	AR	FAT tumor suppressor homolog 1 (cadherin)	Adhesion molecule signalling through RAC1 and CDC42
KIRREL1	AR	Kin of irregular chiasm-like protein 2 (Nephrin-like protein 1)	Interacts with podocin and nephrin at the slit diaphragm
CRB2	AR	Crumbs homolog 2	Regulator of podocyte polarity and nephrin trafficking
Actin binding and regulator of microtubules			
ACTN4	AD	Actinin alpha 4	Interconnects actin filaments in podocyte foot processes
INF2	AD	Inverted formin 2	Diaphanous-related formin governing cellular phenomenon such as actin cytoskeleton remodelling, cell polarity, morphogenesis and cytokinesis
MYO1E	AR	Myosin 1E	Involved in podocyte actin cytoskeleton organization and motility
ARHGDIA	AR	Rho GDP dissociation inhibitor alpha	Involved in cytoskeletal regulation and cell motility
ARHGAP24	AD	Rho GTPase activating protein 24	Actin regulating gene
Regulator of microtubules and transfer RNA modifiers			
WDR73	AR	WD repeat domain 73	Regulation of the microtubule network and cellular architecture
WDR4	AR	WD repeat domain 4	Regulates universal chemical modification of transfer RNA
OSGEP	AR	O-sialoglycoprotein endopeptidase	Regulates universal chemical modification of transfer RNA
TP53RK	AR	TP53 regulating kinase	Regulates universal chemical modification of transfer RNA
TPRKB	AR	TP53RK binding protein	Regulates universal chemical modification of transfer RNA
GON7	AR	GON7 subunit of KEOPS complex	Regulates universal chemical modification of transfer RNA
YRDC	AR	N6-threonylcarbamoyltransferase domain containing	Regulates universal chemical modification of transfer RNA
LAGE3	X linked	L antigen family member 3	Regulates universal chemical modification of transfer RNA
Transcription factors and nuclear genes			
WT1	AD	Wilms tumor 1 transcription factor	Transcription factor regulating urogenital development
SMARCAL1	AR	SWI/SNF related, matrix associated, actin dependent regulator of chromatin, subfamily a like 1	Protein involved in DNA remodelling, critical to stability of DNA replication

AD autosomal dominant, *AR* autosomal recessive.

the glomerular filtration barrier (GFB) integrity with idiopathic or immune-mediated nephrotic syndrome. By light microscopy, the absence of inflammatory lesions and immune complex deposition distinguishes genetic podocytopathies from other secondary causes of disease. Apart from rare congenital forms, the initial presentation of immune-mediated and hereditary podocytopathies is generally similar. However, family history, resistance to immunosuppressive therapy, progression to end-stage kidney disease, and significantly reduced risk of recurrence after kidney transplantation suggest a genetic origin.

Molecular Mechanisms of Monogenic Nephrotic Syndrome

The podocyte is a component of the trilayer GFB; other components are the specialized fenestrated endothelial layer and the glomerular basement membrane (GBM) **(**Fig. 1**)**. Podocytes are terminally differentiated visceral epithelial cells with a cell body, primary, secondary, and tertiary foot processes that interdigitate with neighboring podocytes to form a highly specialized gap junction, the slit diaphragm. Virtually all the genes that are known to cause SRNS/FSGS localize to different parts of the podocyte and disrupt the structure and function of the podocyte **(**Fig. 1**)**. Below is a description of the mechanisms by which mutations in some of these genes will cause disease.

Slit Diaphragm Genes

The podocyte SD is a specialized intercellular junction that connects neighboring podocytes. It is a complex signalling platform that is vital for the maintenance of the structure and function of the podocyte actin cytoskeleton. Morphologically, most podocytopathies are characterized by loss of podocyte slit diaphragm a clear indication of its central role in maintaining the integrity of the glomerular filtration barrier (GFB). The SD was first recognized as a grey line between neighboring podocytes in 1955 on electron microscopy [10]. Its structure was elucidated by elegant transmission electron microscopy studies and was described for the first time as a “zipper like” structure by Karnovsky and Ryan in 1975 [11]. The zipper was described as being formed by molecules from neighboring podocyte foot process that crosses the intercellular space and overlap to form a dense midline structure [12]. The nature of the zipper or the molecular organization of this structure was not unravelled until more than 20 years later when biallelic pathogenic variants in nephrin gene (*NPHS1*) was identified as a cause of congenital nephrotic syndrome [3]. Nephrin is a transmembrane protein and it formed the backbone of the zipper structure of the SD through homophilic interaction with one another. Since these landmark discoveries, multiple genes causing monogenic SRNS/FSGS have been shown to localize to the SD and are known to be important for maintaining the structure, and dynamic intracellular and extracellular signalling at the SD [13–14]. The full repertoire of the molecular components of the podocyte SD is currently unknown; however, desirable properties of the components of the SD include ability to (i) act as a macromolecular filter, (ii) anchor the filter to the GBM, (iii) connect the SD to actin cytoskeleton through adaptor proteins, and (iv) be part of a signalling complex that integrates and mediates extracellular and intracellular signals regulating the plasticity of podocyte foot processes

Fig. 1 **Proteins involved in single gene causation of steroid-resistant nephrotic syndrome (SRNS).** Identification of single gene (monogenic) causes of SRNS has revealed the visceral glomerular epithelial cell, the podocyte, as central to the pathogenesis. This cartoon shows two neighboring podocyte foot processes, which attach to the GBM via laminin/integrin receptors. Recessive monogenic forms of SRNS are in red, and proteins that if mutated cause dominant forms of SRNS are in blue. These SRNS-related proteins were found to be part of protein–protein interaction complexes that participate in defining the structural components or signalling pathways of podocyte function (black frames). These proteins include: laminin/integrin receptors (focal adhesions), actin-binding proteins, glomerular slit membrane-associated components, actin-regulating small GTPases of the Rho/Rac/Cdc42 family, lysosomal proteins, nuclear transcription factors and proteins involved in coenzyme Q10 (CoQ10) biosynthesis. Proteins encoded by recessive SRNS genes include: ADCK4, AarF domain containing kinase 4; ARHGDIA, rho GDP dissociation inhibitor (GDI) alpha; CD2AP, CD2-associated protein; CFH, complement factor H; COQ2, coenzyme Q2 4-hydroxybenzoate polyprenyltransferase; COQ6, coenzyme Q6 monooxygenase 6; CRB2, Crumbs family member 2; DGKE, diacylglycerol kinase epsilon; EMP2, epithelial membrane protein 2; GBM, glomerular basement membrane; ITGA3, integrin, alpha 3; ITGB4, integrin, beta 4; KANK, KN motif and ankyrin repeat domains 1/2/4; LAMB2, laminin, β2; MTTL1, mitochondrial tRNA leucine 1; MYO1E, Homo sapiens myosin 1e; NPHS1, nephrin; NPHS2, podocin; NUP93, nucleoporin 93 kDa; NUP107, nucleoporin 107 kDa; NUP205, nucleoporin 205 kDA; PDSS2, prenyl (decaprenyl) diphosphate synthase, subunit 2; PLCE1, phospholipase C epsilon 1; PTPRO, protein tyrosine phosphatase, receptor type, O; SCARB2, scavenger receptor class B, member 2; SMARCAL1, SWI/SNF related, matrix associated, actin-dependent regulator of chromatin, subfamily a-like 1; WDR73, WD repeat domain 73; XPO5, exportin 5. Proteins encoded by dominant SRNS genes are marked in blue: ACTN4, actinin alpha 4; ANLN, anillin; ARHGAP24, rho GTPase-activating protein 24; INF2, inverted formin 2, LMX1B, LIM homeobox transcription factor 1-beta; MYH9, myosin, heavy chain 9; TRPC6, transient receptor potential cation channel, subfamily C, member 6; WT1, Wilms tumor 1; IQGAP, IQ motif containing GTPase activating protein 1; P, paxillin; V, vinculin and T, talin (Adapted with permission from Lovric S, et al. Genetic testing in steroid-resistant nephrotic syndrome: when and how? Nephrol Dial Transplant 2016;31:1802–13. Oxford University Press)

[12]. Defects in multiple genes that are integral to the structure and function of the SD have been reported; they include nephrin (NPHS1), podocin (NPHS2), CD2-associated protein (CD2AP), transient receptor potential channel 6 (TRPC6), and phospholipase C epsilon 1 (PLCE1).

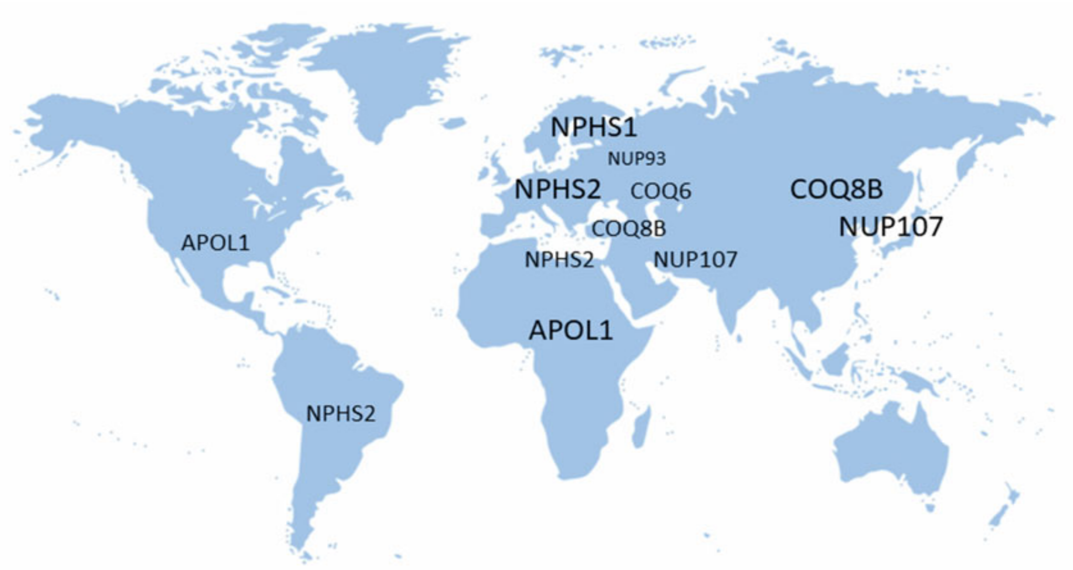

Fig. 2 Geographic distribution of founder mutations in SRNS genes

Nephrin (NPHS1)

Nephrin was identified by positional cloning as a cause of Finnish type congenital nephrotic syndrome in 1998; since then, it has been established that biallelic pathogenic variants in *NPHS1* are found in different populations [3]. Nephrin is a transmembrane protein with a short intracellular domain, a transmembrane domain, and an N-terminal extracellular domain with a proximal type III fibronectin domain and eight IgG like motifs. Homophilic interaction between neighboring nephrin molecules form the zipper-like structure of the slit diaphragm. Nephrin is critical for the formation of podocyte SD, and a SD is absent in both humans and murine models with *NPHS1* defects [12, 14–16]. Nephrin plays a critical role in signalling at the slit diaphragm through phosphorylation of its cytoplasmic tail by tyrosine kinase [15].

Podocin (NPHS2)

The gene *NPHS2* encode for podocin a 383 amino acid protein with a hairpin-like structure with both cytoplasmic, amino, and carboxyl terminal domains [17]. Podocin is an integral membrane protein and it localizes to the insertion site of the podocyte slit diaphragm through a short transmembrane region [18–19]. It is a lipid raft-associated protein belonging to the stomatin family. It also contains a prohibitin homology (PHB) domain, in addition to palmitoylation sites in the hydrophobic region. The palmitoylation sites are required for podocin to bind cholesterol and regulate the activity of associated proteins [20]. Podocin accumulates in oligomeric form in lipid-raft microdomains of the SD plasma membrane where it recruits nephrin thereby augmenting the nephrin-induced activation of the AP-1 transcription factor, and also interacts with CD2AP and TRPC6 [21–24]. The resulting protein complex represents an important link between the SD and podocyte cytoskeleton, and is crucial for structural organization and regulation of filtration function of the SD, mechanosensory signalling, podocyte survival, cell polarity, and cytoskeletal organization [17, 20–24]. Antignac group first reported biallelic pathogenic variants in *NPHS2* as a cause of steroid-resistant nephrotic syndrome [25]. Since then, different reports have shown that mutations in *NPHS2* are the most common cause of autosomal recessive FSGS/SRNS [26–27]. More recently, a founder mutation in *NPHS2* (p.Val260glu) has also been shown to account for a large percentage of SRNS in South Africa [28].

CD2-Associated Protein (CD2AP)

CD2AP is an 80-kilodalton adaptor protein that is critical for stabilizing contacts between T cells and antigen-presenting cells [29]. Mice deficient in CD2AP have been shown to develop nephrotic syndrome and both homozygous and heterozygous *CD2AP* pathogenic variants have been reported in patients with FSGS [29–32]. CD2AP is a scaffold protein that binds nephrin and podocin, and link both to the podocyte actin cytoskeleton [33].

Transient Receptor Potential Channel 6 (TRPC6)

TRPC6 is a nonselective cation channel that is widely expressed but enriched in the podocyte and the SD. Winn et al. reported gain of function mutation in *TRPC6* gene in 2005 as a cause of autosomal dominant FSGS in a New Zealand family [34]. Multiple familial and sporadic cases of FSGS due to *TRPC6* monoallelic pathogenic variants are reported. TRPC6 serves as a chemosensor and mechanosensor that enables podocytes to respond to filtration rate, flow, and pressure changes by remodelling of actin cytoskeleton and foot process contraction with nephrin and podocin to maintain the structure of the SD [18]. TRPC6 activation appears to be mediated by angiotensin II; TRPC6 also interacts with calcium-dependent cystine proteases calpain 1 and 2 to regulate podocyte actin cytoskeleton and motility [16, 35].

Phospholipase C Epsilon 1 (PLCE1)

Biallelic pathogenic variants were reported by Hildebrandt group as a cause of early onset nephrotic syndrome that is characterized by diffuse mesangial sclerosis (DMS) and FSGS on renal biopsy [36, 37]. Interestingly, some individuals in the original report responded to immunomodulation. Follow-up study showed that defects in *PLCE1* might be the most common cause of non-syndromic DMS (diffuse mesangial sclerosis); in addition, another study identified individuals with truncating mutation in *PLCE1* who are asymptomatic suggesting an unusual finding of incomplete penetrance in an autosomal recessive disease [37–38]. PLCε1 is a member of the phospholipase family of enzymes that catalyzes the hydrolysis of polyphosphoinositides to generate second messengers, such as inositol-1,4,5 triphosphate and diacylglycerol [39]. These second messengers are involved in cell growth and differentiation [36–37, 39].

Other genes that localized to and are important for the functions of the SD that have been implicated in the etiology of monogenic NS include *FAT1* (protocadherins), *KIRREL*, and *CRB2* [40–42] (Fig. 1 and Table 1). Studies of hereditary FSGS coupled with staged proteomics and transcriptomic analysis will unravel other key players that are important in maintaining the structure of the podocyte slit diaphragm [43].

Actin Cytoskeleton Genes

The podocyte cytoskeleton is a dynamic network capable of rapid rearrangements; they are finely regulated to maintain the unique octopus-like cell architecture of the podocyte [44–45]. It is composed of microtubules and intermediate vimentin-like filaments in the cell body and primary foot processes and a dense network of microfilaments of actin, myosin, α-actinin, talin, and vinculin in the pedicles [46]. It is bound to the GBM by focal contacts and connected to the SD [47]. As discussed above, the SD is a modified adherens junction that plays an architectural role, but also transmits extracellular signals continuously to the cytoskeleton, underlying the podocyte's plasticity [48].

Alpha Actinin 4 (ACTN4)

ACTN4 encodes the ubiquitous actin-binding protein α-actinin-4 that is highly expressed in podocytes [49]. α-actinin-4 interconnects actin filaments in podocyte foot processes [50]. Most missense monoallelic pathogenic variants in *ACTN4* are located in the residues within or next to the actin-binding site of α-actinin-4 [49, 51]. Some of them have been shown to increase the binding affinity of α-actinin-4 to F-actin, and/or induce α-actinin-4 mislocalization and formation of α-actinin-4 and F-actin aggregates around the nucleus with subsequent impairment of podocyte spreading and motility [49, 51–55].

Knock-in and knockout mouse models and in vitro data suggest both gain-of-function and loss-of-function mechanisms [52].

Inverted Formin Type 2 (INF2)

INF2 encodes for inverted formin 2 a member of the diaphanous-related formin family, with prototypic member being mDia1. Formins are ubiquitous proteins governing various cellular phenomenon such as actin cytoskeleton remodelling, cell polarity, cell morphogenesis, and cytokinesis [56–59]. INF2 contains the formin homology domains FH1/FH2 involved in actin elongation and nucleation, respectively, as well as the diaphanous autoregulatory and inhibitory domains which play a role in INF2 autoinhibition [56–59]. INF2 interacts with the Rho-GTPase Cdc42 and the myelin and lymphocyte protein MAL, both of which are involved in myelination and myelin maintenance [60]. *INF2* variants found in patients with FSGS are found mainly in the inhibitory domain of INF2 encoded by exons 2–4 [56–59]. It has been established in multiple studies that *INF2* monoallelic pathogenic variants are probably the most common cause of autosomal dominant FSGS [56–59]. *INF2* mutations can also cause FSGS associated with the Charcot-Marie-Tooth peripheral neuropathy [60].

Actin-Regulating Protein Rho-GAP 24 (ARHGAP24)

ARHGAP24 encodes the actin-regulating protein Rho-GAP 24, and it is highly expressed in the podocytes [61]. The loss-of-function variant (p. Gln158Arg) causes impaired Rac1-GAP activity of ARHGAP24 [61].

Rho GDP Dissociation Inhibitor α (ARHGDIA)

This gene encodes the Rho GDP dissociation inhibitor α (RhoGDIα) involved in cytoskeletal regulation and cell motility. Biallelic pathogenic variants in *ARHGDIA* are associated with autosomal recessive FSGS and early onset nephrotic syndrome with diffuse mesangial sclerosis and neurological manifestations [62–63]. Interestingly, mouse and zebrafish models can recapitulate the NS phenotype, which can itself be partially rescued by RAC1 inhibitors, paving the way for the therapy of some forms of hereditary NS [62–64].

Myosin 1E (MYO1E)

MYO1E encodes myosin 1E, a member of the ubiquitously expressed class 1 myosins, implicated in podocyte actin cytoskeleton organization and motility. It contains an N-terminal motor-head domain that binds ATP and F-actin, a calmodulin-binding neck domain, and a tail domain with a putative membrane-binding site. It localizes to the podocyte membrane, with enrichment at the lamellipodia tips [65]. MYO1E deficiency in both zebrafish and mouse causes nephrotic syndrome [66–67]. The p. Ala159Pro *MYO1E* variant (affecting a conserved amino-acid residue of the motor-head domain) and the p. Tyr695X* variant (affecting the calmodulin-binding neck domain) were identified in two families with steroid resistance; renal biopsy showed FSGS, focal thickening and disorganization of the GBM, and focal expansion of the mesangial matrix [65]. These lesions were very similar to those of *myo1e* knock-out mice. Myosin 1E is the second myosin identified in the podocyte after the heavy chain of myosin IIA. Non-muscular myosins generate intracellular tension and their interaction with actin could allow the pedicles to counteract the intraluminal hydrostatic pressure, resulting in podocyte plasticity [68–69].

Regulators of Microtubule.

WDR73

WDR73 encodes a WD40-repeated-containing protein that may play a role in the regulation of the microtubule network and cellular architecture, cell cycle, and cell survival. It is located along the microtubules during the interphase and at the spindle poles and astral microtubules during mitosis. Zebrafish embryos inactivated for *wdr73* by morpholinos show a deficit in brain growth resulting from a defect in neural progenitor cell proliferation and differentiation [70–71]. *WDR73* pathogenic variants result in Galloway-Mowat syndrome, a recessive neurorenal disorder with microcephaly and nephrotic syndrome [70–71].

Transcription Factors and Nuclear Genes.

WT1

Wilms tumor 1 gene encodes a transcription factor of the zinc finger family which is the major factor involved in cell differentiation and survival in the developing kidney, urinary tract, and gonads. Its expression persists in podocytes in the adult kidney, and it is required for proper function of the podocyte and the GFB [72]. For that reason, individuals with *WT1* gene defects typically present with a wide range of clinical findings that include glomerulopathy, disorders of testicular development, congenital anomalies of the kidney and urinary tract (CAKUT), nephroblastoma, and gonadoblastoma. While various combinations of findings were designated as certain syndromes (Denys-Drash, Frasier, Meacham or chromosome 11p13 microdeletion), those designations are now recognized as part of a phenotypic continuum and are no longer clinically helpful [73].

LMX1B

LMX1B gene encodes a LIM-homeodomain transcription factor that directs dorsoventral patterning of limb development and formation of the anterior eye and the podocytes [74]. Loss-of-function variants in *LMX1B* gene cause nail-patella syndrome, which presents as dysplastic changes in the nails, knees, elbows, and the presence of iliac horns. Renal involvement occurs in 30–50% of affected individuals with ~15% reaching ESKD in adulthood. Individuals carrying mutations affecting the homeodomain responsible for DNA binding tend to present with nephropathy and minimal skeletal involvement [75]. Variants affecting the p. Arg246 (R246) residue in particular tend to cause FSGS without extrarenal manifestations [75]. The molecular mechanisms of this renal-limited phenotype is unclear; one study showed that the p.Arg246Gln exerted dominant negative and haploinsufficiency effects on the expression of podocyte genes such as *NPHS1, GLEPP1, and WT1* compared with wild-type *LMX1B* [76]. Specifically, the variant mediated downregulation of WT1(-KTS) isoforms in podocytes [76].

SMARCAL1

SMARCAL1 encodes the SWI/SNF-related, matrix-associated, actin-dependent regulator of chromatin subfamily A-like protein-1 from the SWI2/SNF2 family of ATP-dependent chromatin remodelling proteins. SMARCAL1 uses energy from DNA-activated ATP hydrolysis for DNA remodelling, especially the replication forks, and is critical for stable DNA replication [77]. Biallelic pathogenic variants classically cause multiorgan disorder with progressive glomerulopathy, spondyloepiphyseal dysplasia leading to short stature and peculiar dysmorphic features, defective cellular immunity, bone marrow failure, and cerebral infarcts. However, systemic features are variable with the exception of inevitable progressive kidney disease and end-stage kidney disease [78].

Transfer RNA Modifiers.

Transfer RNAs (tRNAs) are key players in protein synthesis because they decode genetic information organized into messenger RNA codons, translating them into 20 different amino acids. To be active, tRNAs undergo important posttranscriptional modifications. The t6A modification (N6-threonylcarbamoyladenosine) is one of the few universally conserved tRNA modifications implicated in efficiency and fidelity of translation impacting protein synthesis and cellular proteostasis. The t6A modification is catalyzed by YRDC and OSGEP, the latter being part of the multiprotein KEOPS complex. The KEOPS complex contains five subunits LAGE3, OSGEP, TP53RK, TPRKB, and GON7. Recessive pathogenic variants in the autosomal *OSGEP, TP53RK, TPRKB, GON7, YRDC,* or X-linked *LAGE3* genes are associated with Galloway-Mowat syndrome, the phenotypically heterogeneous disorder characterized by neurodevelopmental defects, dysmorphic features and microcephaly with podocytopathy [79]. YRDC and KEOPS subunit defects affect podocyte and neuron proliferation and migration through a decrease in t6A levels and protein synthesis. The fundamental role of the KEOPS complex in cell maintenance is supported by the observation that none of the affected individuals with autosomal recessive pathogenic variants carried two truncating alleles in the mutated gene. *WDR4* encodes a component of the METTL1/WDR4 holoenzyme, involved in the regulation of the highly conserved N7-methylguanosine (m7G) posttranscriptional tRNA modification. *WDR4* biallelic pathogenic variants also cause autosomal recessive forms of Galloway-Mowat disease [80]. This is the second entity of the disease that can be attributed to alteration in a tRNA-modifying enzyme confirming the major role of tRNA modifications in podocyte and neuron physiology.

Nucleoporin Genes

Nuclear pore complex (NPC) proteins (nucleoporins, NUPs) are a class of ~30 proteins that assemble to form NPCs. NPCs serve as the channels that span the nuclear envelope and allow bidirectional nuclear translocation processes. They form a basket-like structure facilitating the transport of proteins, RNAs, and ribonucleoprotein particles between the cytoplasm and interior of the nucleus, hence controlling nucleocytoplasmic transport. In addition, they are also involved in chromatin organization and epigenetic processes [81]. Pathogenic mutations in a number of genes encoding nucleoporins namely: *NUP85, NUP93, NUP107, NUP133, NUP160, NUP205*, and *XPO5* (encoding the NUP-interacting protein exportin 5) were recently described to cause childhood-onset SRNS [7, 82].

Mitochondria Genes

Mitochondriopathies are a diverse group of disorders due to structural, biochemical, or genetic derangements of mitochondria [83]. Renal dysfunction is rare and may result from pathogenic variants encoded by the mitochondrial or nuclear genomes. The mitochondrial genome codes for 13 essential subunits of the mitochondrial respiratory chain, and the 22 transfer RNA (tRNA) and 2 ribosomal RNA (rRNA) genes [84]. Mutations in the mitochondrial sequence encoding tRNA for leucine (UUR) may lead to a wide range of features including MELAS (mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke-like syndrome), diabetes mellitus associated with sensorineural hearing loss or an isolated nephropathy. Nuclear genes that can cause syndromic or isolated steroid resistance encode proteins of the coenzyme Q10 pathway [85].

Coenzyme Q10 (COQ10, ubiquinone) is a lipid-soluble component of all cell membranes, vital for transport of electrons from complexes I and II to complex III of the mitochondrial respiratory chain, a potent antioxidant and co-factor of mitochondrial dehydrogenases and pyrimidine synthesis proteins [86]. At least 10 enzymes are required for CoQ10 synthesis, which, when mutated, lead to heterogeneous multisystemic disorders including myopathy, seizures, ataxia, deafness, optic atrophy, and cardiomyopathy. Steroid-resistant nephrotic syndrome may develop in patients with CoQ10 deficiency with or without extrarenal features, due to biallelic pathogenic variants *in COQ2, COQ6, PDSS2,* or *COQ8B* [85]. Since the products of these genes have been identified as being important in the synthesis of CoQ10, supplementation with CoQ10 may be therapeutic.

Integrin, Adhesion, and Laminin Genes.

LAMB2

LAMB2 gene encodes for laminin beta 2, an important component of the GBM. Using homozygosity mapping, *LAMB2* truncating biallelic pathogenic variants were identified in families with Pierson syndrome [87]. The syndrome is characterized by congenital nephrotic syndrome with diffuse mesangial sclerosis and an irregular GBM on kidney biopsy, ocular anomalies mostly microcoria, and developmental delay [87–89]. *LAMB2* defects can cause both syndromic and non-syndromic early onset nephrotic syndrome [90–94]. Laminins are heterotrimeric extracellular matrix proteins that provide the basic scaffold for assembly of other components of the GBM, including type IV collagen, nidogen/entactin, and sulfated proteoglycans [95]. Mice that are deficient in *lamb2* recapitulate the features observed in patients with Pierson syndrome [96]. Interestingly, proteinuria precedes podocyte foot process effacement in these mice suggesting that SD integrity is not sufficient to maintain proper glomerular filtration functions [97]. It should be noted that overexpression of *lamb1* in *lamb2* null mice prevents development of nephrotic syndrome and extend lifespan suggesting that this may be a therapeutic target for nephrotic syndrome due to *LAMB2* mutation [98].

ITGB4 and other integrin genes: Pathogenic variants have been reported in *ITGB4* encoding for the integrin beta 4 subunit in children with syndromic nephrotic syndrome associated with junctional epidermolysis bullosa [99–102]. The mechanisms by which variants in this gene induce glomerular disease are unknown.

Pathogenic variants have also been reported in *LAMB3, ITGA3*, and *CD151* in children with epidermolysis bullosa and nephrotic syndrome [103–105]. The integrin α3 subunit heterodimerizes with the β1 subunit to form integrin α3β1 expressed at high levels in podocytes, where it associates with the tetraspanin, CD151 [104–109] and binds laminins [105–111]. CD151 strongly interacts with integrin α3β1 and is distributed along the GBM [107–110]. Finally, Cd151null mice recapitulate the phenotype seen in humans [112–113].

Genes Associated with Other Renal Phenotypes

Apart from the genes reported above, genes associated with other renal phenotypes have also been reported as genetic causes of SRNS/FSGS. Searching for causative genetic defects in a pedigree of three sisters referred for familial SRNS diagnosed between 8 and 13 years of age and FSGS on biopsy, Gbadegesin's group identified two compound heterozygous variants of *COL4A3* segregating with the disease and showed that 10% of families diagnosed with familial FSGS have pathogenic variants in *COL4A3* or *COL4A4* genes [114]. These findings have been confirmed in other cohorts around the world [115–117]. These data emphasize the need to screen for pathogenic variants in *COL4A3, COL4A4, and COL4A5* in patients with familial FSGS, especially in those with microscopic hematuria or deafness. Pathogenic variants in *COL4A3* and *COL4A4* are responsible for Alport syndrome of autosomal dominant or recessive inheritance, while pathogenic variants in *COL4A5* is responsible for classic X-linked Alport syndrome. The mechanisms by which defects in *COL4A* genes will produce a predominant podocytopathy phenotype is not completely known, but the effect of modifier genes cannot be ruled out. Other proposed mechanisms include altered permselectivity of GBM, abnormal matrix–podocyte interactions, and defective expression or trafficking of GBM matrix components [114]. In addition, abnormal COL4A may not be able to engage integrin on podocyte effectively [118]. Other monogenic kidney disease genes that have been reported to phenocopy FSGS or podocytopathy include mutations in *TTC21B* (a ciliopathy gene) [119], *CLCN5* (cause of Dent disease) [120], and *PAX2* (a congenital anomaly of the kidney and urinary tract: CAKUT gene) [121–122].

Complex Inheritance

A significant fraction of SRNS is due to an underlying monogenic defect; conversely most cases of steroid responsive nephrotic syndrome are likely due to complex interaction between multiple genetic variants (common and rare) and environmental factors, so-called "complex inheritance." The best way to unravel these variants is by genome wide association studies (GWAS). Unfortunately, there are few GWAS focusing exclusively on idiopathic nephrotic syndrome or FSGS. The few published studies have provided exciting data on the genetic architecture of nephrotic syndrome. Example of recent successes are GWAS in people of African ancestry with FSGS and childhood onset steroid sensitive nephrotic syndrome (SSNS).

FSGS in African Americans

Multiple epidemiologic studies in the USA have reported excess of chronic kidney disease and more specifically FSGS in people of African ancestry. Factors associated with this obvious disparity include unknown genetic factors, social status (wealth, education, and employment status), provider factors (implicit bias), and healthcare factors (access to care or mistrust of the healthcare system) [123]. In a landmark study in 2010, the genetic basis for high prevalence of FSGS in African Americans (AA) was established when variants in the gene *apolipoprotein L-1 (APOL1)* were reported to confer 10 times odds of developing FSGS among AA [122]. Two alleles termed "G1 and G2" were reported almost exclusively in people of African ancestry. The G1 allele are two non-synonymous variants that are almost in complete linkage disequilibrium (p.Ser342Gly, p.Ile384Met) and the G2 allele is an in-frame 6-nucleotide deletion (p.Asn388_Tyr389del). *APOL1* encodes a protein that causes lysis of trypanosome the cause of African sleeping sickness. The G1 and the G2 allele provide survival advantage for fatal African sleeping sickness analogous to protection conferred against malaria by sickle cell trait. However, homozygous and compound heterozygous genotype predispose to FSGS and other chronic kidney diseases. Since its original description, the high-risk genotype has been associated with chronic kidney diseases such as HIV-associated nephropathy (HIVAN), sickle cell disease nephropathy (SCDN), and lupus nephritis [124–125]. Limited studies in AA children showed that just like in adults, *APOL1* high-risk genotype is a major risk factor for SRNS/FSGS [126–129]. Although high-risk genotype for *APOL1* is highly penetrant for a polygenic disease risk allele, it should be noted, however, that only about 25% of individuals with high-risk *APOL1* genotype go on to develop CKD, suggesting that there are disease modifiers associated with APOL1-associated nephropathy. The mechanisms by which *APOL1* variants may predispose to FSGS are not unravelled; however, there are suggestions from in vitro and in vivo studies that the variants may predispose to disease by increased expression of APOL1 in the kidney, NLRP3 inflammasome activation, mitochondrial dysfunction, aberrant efflux of intracellular potassium, defective endolysosomal trafficking, and endoplasmic reticulum stress [130–136]. Compounds that can downregulate APOL1 expression are being developed for treatment and prevention of APOL1-associated nephropathy [137].

Childhood Steroid Sensitive Nephrotic Syndrome (SSNS)

SSNS is a relatively rare disease with prevalence of 16 cases per 100,000 children; it is therefore difficult to assemble a large cohort to carry out GWAS study to identify disease risk loci. It is a complex trait that occurs and is determined by the combined effect of different alleles in many genes and interaction with numerous environmental factors such as lifestyle, diet, exposure to certain pathogens, and other factors. Gbadegesin and his group identified variants in *HLA-DQA1* gene as risk locus for SSNS in a modest cohort of South Asian children [138]. Since then, four other studies have confirmed these findings and reported other loci in the HLA region [139–142]. More recent studies have identified variants in *CALHM6* (calcium homeostasis modulator family member 6), *TNFSF15* (tumor necrosis factor superfamily member 15) that are outside the HLA region, but associated with regulation of immune response, as risk loci for SSNS [140–142]. A study from Japan showed that common variants in *NPHS1* (nephrin) are associated with SSNS suggesting that the same gene can cause or contribute to both monogenic disease (congenital nephrotic syndrome) and a more complex, polygenic disease like SSNS [142]. Findings from these association studies emphasize the role of adaptive immunity in the pathogenesis of SSNS. Larger meta-analyses may lead to identification of additional loci and pathways that may be targets for novel and specific therapy.

Implications on Disease Stratification and Diagnosis

Current Classification

Idiopathic nephrotic syndrome, defined by the classic triad of proteinuria, edema, and hypoalbuminemia, is classified according to clinical/observational criteria, which have little known relevance to underlying molecular mechanisms.

There are two main ways of stratification by these means, either by response to steroids or light microscopic appearance of a kidney biopsy. In children, it is more common to classify according to steroid response (steroid sensitive, steroid dependent/frequent relapsing, and steroid resistant) partly because not all patients are biopsied. Findings on biopsy do not always correlate with patterns of steroid responsiveness, though FSGS is usually associated with resistance to steroids and nonresponse to immunomodulators.

Stratification Based on Diagnosis of Single Gene Mutations

The discovery of genetic defects causing nephrotic syndrome has provided molecular insight into the disease. Pathogenic variants associated with nephrotic syndrome have been described in over 60 genes, some causing isolated kidney disease, while others are associated with features in other organ systems (syndromic disease).

Patients with genetic nephrotic syndrome behave distinctly from nongenetic disease, which is assumed to be immune mediated [143–144]. The former rarely if ever responds to immunosuppression, with scattered reports in cases that have partially or rarely completely responded. The latter includes patients with *PLCE1* or *WT1* pathogenic variants. Several series are reported where a small proportion of patients with monogenic nephrotic syndrome respond partially or rarely completely, but it can be difficult to distinguish those responses from the natural fluctuations in disease course, or to be confident that all reported variants are pathogenic [143]. Larger series where patients have been comprehensively tested suggest that the actual response rate to immunosuppression in genetic nephrotic syndrome is negligible [143–145]. This suggests that genetic nephrotic syndrome is a different mechanistic group from nongenetic illness and is further backed up by differences in outcome posttransplantation.

In SRNS, most patients reach end-stage kidney disease and require transplantation. In this group, approximately 30–40% will get rapid posttransplant allograft recurrence of the disease, suggesting the presence of a pathogenic circulating factor in the recipient. Focused clinical and genetic screening of SRNS patients has clarified that “circulating factor disease” is a distinct entity from genetic NS, and the former can be better predicted using certain phenotypic criteria alongside genetic testing. The best clinical predictor to date is of patients with secondary steroid resistance (initial steroid sensitivity with late resistance) where patients who initially completely respond to standard steroid therapy become steroid resistant during the course of their disease. Up to 90% of these patients will suffer disease recurrence posttransplantation [146–147].

Comprehensive genetic screening is widely available and allows clinicians the first level of stratification at presentation, where a rapid diagnosis allows decisions on the level of immunosuppression, as well as prognostic ability to predict posttransplant recurrence, and provide information on how fast specific genetic mutations will progress.

Immune-Based Nephrotic Syndrome

In non-monogenic nephrotic syndrome, there is still evidence that underlying genetic architecture plays a significant part in driving the disease process. For example, there are at least 22 reported single nucleotide variants in different genes, which are present in significantly higher frequency among cohorts of patients with idiopathic nephrotic syndrome than in healthy controls (complex inheritance). These polygenic risk variants are genetic variants that individually are insufficient to cause a disease but create a high-risk disease genotype when combined with other genetic and environmental factors. These genetic factors may represent genetic modifiers that render a patient susceptible to (or protected from) developing nephrotic syndrome. Most consistent among these are the HLA genes, particularly *HLA-DQA1, HLA-DRB1, and HLA-DQB1*, mainly derived from GWAS approaches, and implying a close link with the immune system [138–142]. This begins to lead to important clues towards genetic modifiers that could be used for further stratification approaches. In other diseases, such as diabetes, GWAS has led to the identification of genetic loci that associate with disease and disease subtypes. This has permitted the development of "genetic risk scores" by assigning weighted scores to each genetic locus, and by combining the score for each individual patient a "risk" of having for example type 1 diabetes [148]. Similar scores may be derived for nephrotic syndrome, that align with pattern of steroid response, or circulating factor disease.

Circulating Factor Disease

The other unique aspect of nephrotic syndrome biology that can be exploited is the observation that a proportion of cases are caused by a circulating factor (or factors) that should in theory be detectable in a blood sample. The target of such factor(s) is the podocyte, so a biomarker based on in vitro assays of human podocytes exposed to patient plasma samples has been a goal of scientific efforts. The readouts include molecular pathways within the podocyte that are activated by disease relapse plasma, with specificity, that distinguishes the disease from off-target effects of human plasma, and that therefore will distinguish circulating factor disease from genetic and other causes of nephrotic syndrome. To date, there is no clear evidence of any single gene mutation being a cause of circulating factor disease. Evidence for this includes the lack of patients with familial recurrence of nephrotic syndrome post-transplantation. Additionally, the premise that circulating factor disease is separate from monogenic disease is further supported by exome sequencing findings from UK cohort of patients with SRNS**.** None of the 25 patients who were initially steroid sensitive had monogenic disease, but 4 of 5 patients had post-transplant recurrence, the archetypal circulating factor disease [143]. This study also identified 108 patients who screened negative for monogenic disease but presented with primary steroid resistance. This group had a high rate of progression to ESKD and a greater than 50% rate of recurrence post-transplantation, suggesting that at least half of those patients have a circulating factor. The remainder could have a yet undiscovered monogenic disease or another unsuspected mechanism of disease.

Other Means of Stratification Based on Molecular Signatures

As our ability to generate and process "big data" from patients with nephrotic syndrome grows, the opportunities for molecular classification has increased [149]. Our biological datasets have comprised of histology, urinary sediment, and plasma chemistry. Genetic sequencing information is now at the vanguard of new perspectives of the disease, utilizing omics technologies. Insights are being made with, e.g., proteomics analysis of biopsy tissue; RNA sequencing of lymphocytes; epigenetic profiling; and metabolomics of patient plasma. The opportunity now is to integrate these diverse datasets to develop molecular signatures for subsets of disease that correlate with the underlying mechanistic drivers. This will lead ultimately to our ability to target both new and existing therapeutic drugs to the patients most likely to benefit, based on molecular pathways involved.

Diagnostic Implications

The discovery of more than 60 genes that can cause SRNS when mutated, alongside the advent of next generation sequencing technology means that clinical genetic screening for patients is now a feasible in clinical practice [150]. Various laboratories have been set up for specific gene panel tests, based on NGS technology and covering some or all of the known genes. Results are available within weeks; these advances have implications for clinicians and patients. Firstly, it is important for clinicians to become familiar with interpretation of results from these reports. Results can be reported using a variety of templates, containing different amounts, levels, and layouts of information. There are multiple levels of uncertainty surrounding the result itself (e.g., testing error) and what it actually means (e.g., variant significance). Guidelines for genetic test reporting are available from the American College of Medical Genetics and Genomics (ACMG), European Society of Human Genetics (ESHG), and Association for Clinical Genetic Science (ACGS) [151–153].

Clear communication of the uncertainties inherent in reports to parents and patients is crucial, and the support of clinical geneticists is often required. Finally, the availability of a rapid genetic test at the time of initial presentation could mean that a diagnostic biopsy can be delayed or avoided, depending on the speed of that result.

The question on who to test is pertinent, given that gene panel testing is relatively inexpensive, and that at least 10–30% of incident patients with SRNS are found to have defects in a single gene responsible for their disease [143, 154]. The cost-benefit ratio strongly advocates routine genetic testing for all children presenting with SRNS. To date, patients with secondary (late) SRNS or SSNS have not been found to have any of the known genetic variants associated with their disease, so routine testing in those groups is not advocated [155]. Genetic testing in SRNS patients presenting in adulthood is less common, and data is scarce. However, recent studies have suggested that in patients with sporadic SRNS with no family history or syndromic features, there is 11–12% incidence of monogenic disease [156–157]. The majority of these present in younger adults, and pathogenic variants are predominantly in *COL4A* genes, illustrating the phenotypic variability of mutations and suggesting that focused gene testing is an alternative way of picking up the majority of genetic diagnoses in the adult population.

Future Directions

New genes continue to be discovered that cause SRNS when mutated, though it is probably safe to say that the majority of disease-causing genes in terms of patient numbers have been identified, at least in the major population groups. The remaining discoveries will mostly be "private" mutations, meaning the genes/mutations will only affect a handful of patients and pedigrees.

Genetic testing now needs to be widespread, rapid, and routine, so that it is embedded into the clinical pathway, and granular understanding of whether specific mutations may respond to existing immunotherapies is required. Collaborative analysis of genotype/phenotype across the world through registries will enable stratification of SRNS, at the level of genetic versus immune disease, and at the level of clinical outcomes for specific genes and variants. A major challenge is the development of specific therapies, based on molecular understanding from study of the newly discovered proteins and pathways. Examples include inhibitors of channels, for example, TRPC6 and TRPC5, or chaperones for misfolding and hence mistrafficked proteins [158–159]. Another approach is by gene therapy technologies, which have been applied successfully for monogenic diseases in other organ systems, for example hemophilia A or spinal muscular atrophy. The major challenge is targeting of viral vectors to the specific affected cell – the podocyte.

In summary, the discovery of genetic causes for SRNS over the last 20 years has transformed not only our understanding of the biology of the glomerular filtration barrier but also transformed patient diagnostic pathways and care.

Abstract

Children with congenital nephrotic syndrome (CNS) present within the first 3 months of life. Primary CNS is typically caused by mutations in genes encoding for components of the glomerular filtration barrier. The classical form is the Finnish type of CNS (CNF, NPHS1) caused by mutations in *NPHS1* (nephrin) gene, and it typically causes heavy proteinuria in the newborn period. Pathogenic variants in other genes namely *NPHS2* (podocin), *WT1* (Wilms tumor suppressor 1), *LAMB2* (laminin β2), and *PLCE1* (phospholipase C epsilon 1, NPHS3) can also cause CNS, which have more variable clinical manifestations including a wider age range at disease onset. Mutations in these five genes together account for >80% of CNS patients. Besides genetic causes, CNS can be secondary to other diseases like congenital infections or immune disorders. The diagnosis of CNS and its underlying etiology is based on several features including clinical presentation, family history, laboratory findings, genetic testing, and histology. While medical management is possible for certain forms of secondary CNS, kidney transplantation is the only curative treatment for most patients with genetic CNS. In unstable patients with refractory nephrotic states, bilateral nephrectomy and dialysis followed by transplantation may be considered after they attain body weights of 7–10 kg. In stable patients, nephrectomy is not needed, and renal replacement therapy is commenced when they reach end-stage kidney disease (ESKD). Transplantation should be performed when the patient is no longer nephrotic. The outcome of transplantation in CNS patients is satisfactory, and comparable to other pediatric kidney patients.

Synonyms

CNF: Congenital nephrotic syndrome of the Finnish type

Congenital nephrotic syndrome (CNS) is defined by the presence of heavy proteinuria, hypoalbuminemia and severe edema, manifesting in utero or in the first 3 months of life. The etiology of CNS is broadly classified into primary causes mostly due to genetic defects, and secondary causes due to systemic disease.

Primary Nephrotic Syndrome

Nephrin (*NPHS1*) and CNS of the Finnish Type (CNF)

The *NPHS1* gene, which encodes the cell adhesion protein called nephrin, was first discovered in 1998 to be the cause of CNS of the Finnish type (CNF) [1]. CNF is a severe form of CNS typically seen in Finnish newborns [2] with an incidence of 1:8200 live births [1, 2]. Since the discovery of nephrin, both CNF and NPHS1 (nephrotic syndrome type 1) were used interchangeably as abbreviations for this disorder. Nephrin localizes to the slit diaphragm and plays an important role in the glomerular filtration process. Two important founder *NPHS1* mutations, Fin-major (c.121delCT; p.L41fs) and Fin-minor (c.3325C_T; p.R1109X), were observed in over 90% of patients with CNF [1]. Both mutations result in stop codons and truncated proteins not expressed in the podocyte slit diaphragm. These mutations are rare outside Finland.

More than 200 *NPHS1* mutations have been reported in non-Finnish CNS patients. They account for the majority (40–80%) of patients with CNS worldwide [3–6]. Most mutations found in non-Finnish patients are missense mutations, though deletions, insertions, nonsense, and splice site changes spanning across the whole gene occur too. Many missense *NPHS1* mutations cause misfolding of the protein and defective intracellular transport resulting in retention of the mutant protein in the endoplasmic reticulum, and absence of nephrin in the slit diaphragm [7]. This may explain why missense *NPHS1* mutations, though considered as "mild," can cause heavy proteinuria and severe CNS [8–10]. Nephrotic syndrome is diagnosed within the first week of life in 82% of the infants with *NPHS1* defects and within 2 months in the rest of the cases. In a European study, all patients with *NPHS1* mutations manifested within the first 90 days [3].

There is no renal histology pathognomonic for *NPHS1* but the most characteristic histological findings are expansion of the glomerular mesangium and irregular microcystic dilations in the proximal tubules [8, 9]. Electron microscopic examination show effacement of the podocyte foot processes and absent podocyte slit diaphragm [10]. Within the first 1–2 years, glomerular sclerosis, interstitial fibrosis, and inflammatory infiltrates increase [9]. Infants with *NPHS1* genetic defects do not have extrarenal malformations [8]. However, minor functional disorders in the central nervous system and heart are common during the nephrotic stage. Most children have hypotonia. Mild atrophic brain changes were seen in a third of the infants with *NPHS1* defects and dystonic cerebral palsy in 8% of Finnish patients. The pathogenesis of these is not known. Minor cardiac findings such as hypertrophy and mild pulmonary stenosis have also been reported in patients with CNF [8]. A subset of patients with certain *NPHS1* variants has been reported to have milder clinical course [4, 11]. In addition, some patients respond to therapy with angiotensin-converting enzyme inhibitors (ACEi) and indomethacin with residual mild proteinuria [8].

Podocin (*NPHS2*)

The *NPHS2* gene, encoding for the protein podocin, is a common cause of steroid-resistant nephrotic syndrome in children and adults. It is the second most common gene (17–39%) implicated in CNS cases after *NPHS1* [12–15]. Patients with *NPHS2* pathogenic variants present later compared to variants in *NPHS1* [3]. Among all European patients with CNS presenting in the first week of life, only 11% had *NPHS2* defects while 74% had *NPHS1* variants. Among those presenting with nephrotic syndrome after 1-month of age, *NPHS2* accounted for 37%, whereas *NPHS1* variants were present in 16% [4]. The prevalence of *NPHS2* mutations differs in different ethnic groups. None of the 25 Turkish patients with CNS carried *NPHS2* mutations, while 54% of central European infants with CNS carried *NPHS2* pathogenic variants [3]. Studies in Asia suggest that *NPHS2* mutations are relatively rare in patients with CNS (0–8%) [13, 16, 17].

The severity of proteinuria and clinical findings are more variable than in patients with *NPHS1* defects. Although most patients with *NPHS2* mutations presenting in later childhood have focal segmental glomerulosclerosis (FSGS), CNS patients with *NPHS2* mutations often show minimal histological changes, and <50% have FSGS [4]. Progression to ESKD is less rapid for CNS patients with *NPHS2* mutations (mean 6.6 years) compared to *NPHS1* mutations (mean 4.6 years) [3]. As *NPHS2* is only expressed in the podocytes, extrarenal manifestations are unlikely.

Wilms Tumor Suppressor 1 (*WT1*)

Wilms tumor suppressor gene (*WT1*) encodes for a nuclear WT1 protein, a transcription factor that plays a crucial role in the embryonic development of the kidney and genitalia. Being an autosomal dominant gene, heterozygous *WT1* genetic defects account for 2–13% of cases with CNS [6, 18]. Missense mutations in exons 8 or 9 impair the DNA-binding capacity of the WT1 protein and can result in Denys-Drash syndrome that is characterized by early nephrotic syndrome with diffuse mesangial sclerosis, male pseudohermaphroditism, Wilms tumor, and gonadoblastoma. Truncating genetic variants are associated with highest risk of Wilms tumor, while missense variants affecting the DNA-binding sites are associated with early disease onset and rapid progression to ESKD. Male pseudohermaphroditism with the highest risk of gonadal malignancy occurs exclusively in patients with missense variants at the DNA-binding sites. Unlike syndromic cases which can occur in both male and female phenotypic patients, the non-syndromic isolated nephrotic syndrome that manifests at varying ages, occur exclusively in genotypic and phenotypic females [19].

Patients with *WT1* mutations have varying degrees of proteinuria and are less symptomatic at disease onset with less marked edema and hypoalbuminemia compared to other genetic diagnosis. While they tend to have larger placentas compared to normal infants, their placenta (placental/fetal weight 18%) are significantly smaller compared to patients with CNF (placental/fetal weight >25%). Patients with Denys-Drash syndrome are likely to have higher serum creatinine at onset compared to CNF [18]. The characteristic and commonest glomerular lesion is diffuse mesangial sclerosis, although FSGS and minimal change disease can also occur [19]. Urogenital abnormalities are common.

Because of the significant and early risks of Wilms tumor (55–74%) [20, 21], the management of patients with *WT1* variants is different from other CNS patients. Prophylactic bilateral nephrectomy after onset of ESKD is recommended. A pediatric endocrinologist should be involved in the multidisciplinary care, and prophylactic bilateral gonadectomy should be considered.

Laminin β2 (*LAMB2*)

LAMB2 encodes the laminin β2-chain that is expressed in the glomerular basement membranes (GBM), ocular structures, and neuromuscular synapses. *LAMB2* genetic variants account for 1.7–5% of patients with CNS [3, 6, 22]. Majority of *LAMB2* mutations are truncating with loss of function and can occur along the entire gene. Patients with *LAMB2* genetic defects classically present with Pierson syndrome which is characterized by early onset nephrotic syndrome associated with distinct ocular malformations [23, 24]. Rapid progression to ESKD may occur during the first few weeks or months of life.

The characteristic ocular feature is microcoria manifesting as fixed extreme narrowing of the pupils. Other ocular manifestations include abnormalities of the lens, cornea, and retina; patients often develop blindness. Patients who survive the newborn period may develop neurological deficits, including severe hypotonia and psychomotor retardation. On the other hand, missense *LAMB2* variants and small in-frame deletions cause a milder phenotype (e.g., milder ocular changes, slower ESKD progression) [24]. *LAMB2* variants rarely cause isolated nephrotic syndrome [3, 24].

In a large cohort of 51 patients from 39 unrelated families, 90% of patients with *LAMB2* mutations presented in the first 3-months of life [25]. Diffuse mesangial sclerosis was the major histological finding, though some had FSGS. Microcoria or other ocular abnormalities were detected in most patients. Microcephaly or neurodevelopmental deficits were present in 10% and 50% patients, respectively [25].

Phospholipase C Epsilon 1 (PLCε1)

Mutations in the phospholipase C epsilon 1 (*PLCE1*) gene cause an autosomal recessive form of early-onset nephrotic syndrome [26]. PLCε1 is a phospholipase enzyme and may be involved in slit diaphragm signaling and the function of the glomerular filter. The absence of PLCe1 may halt glomerular development leading to lesions resembling diffuse mesangial sclerosis. Mutations in *PLCE1* were originally reported in 14 patients from 7 families with isolated SRNS manifesting between 2 months to 9 years [26]. Two patients with truncating *PLCE1* genetic variants achieved full and sustained remission with cyclosporine A or steroids. Truncating *PLCE1* mutations were found in 29% of a worldwide cohort of children with “idiopathic” diffuse mesangial sclerosis manifesting between 1 and 36 months [27]. Among CNS, *PLCE1* pathogenic variants accounted for 4.4% cases [3]. While diffuse mesangial sclerosis is the chief histology, FSGS may also be found. Incomplete penetrance occurs, suggesting that other factors might modify the effects of *PLCE1* variations [6]. No extrarenal manifestations are noted in patients with *PLCE1* genetic variants.

Other Genes

Galloway-Mowat syndrome, an autosomal recessive condition, is characterized by nephrotic syndrome, severe neurological abnormalities and microcephaly at birth. Brain abnormalities include neuronal-migration abnormalities such as agyria or microgyria, which lead to severe psychomotor developmental delay and seizures. The patients may also present dysmorphic features such as hypertelorism, ear abnormalities, and micrognathia. Most die in early childhood. Truncating variants in the *WDR73* gene were first described as the cause of the disorder [28]. More recently, pathogenic variants in *OSGEP*, *LAGE3*, *TP53RK*, and *TPRKB* genes have also been identified as monogenic causes of the disease. These genes encode the four subunits of KEOPS complex, which plays an important role in the brain and renal development [29].

Mitochondrial disorders can cause glomerulopathy. These are broadly divided into two major types: defects in a nuclear gene, namely *COQ2*, *PDSS2*, *COQ6*, *ADCK4*, or *PDSS1,* encoding proteins in coenzyme Q10 (CoQ10) biosynthesis pathway (autosomal recessive inheritance), and those caused by mitochondrial DNA 3243 A > G mutation in the tRNALeu (UUR) gene (maternal inheritance). These patients show FSGS that may be collapsing or associated with crescents. Patients with CoQ10 biosynthetic defects may have a glomerulopathy occurring either in isolation or as part of a multisystemic disease. The coexistence of neuromuscular symptoms with renal defects raises the suspicion of a mitochondrial disorder. Age of onset varies and may be within the neonatal period [30]. The first symptoms of mitochondrial disorder develop within the first few weeks of life in about one-third of patients. In CoQ10 biosynthetic defects, treatment with high doses of CoQ10 at 30–50 mg/kg/day can reduce proteinuria, improve symptoms of nephrotic syndrome, and slow progression of the disease [31, 32].

SGPL1 encodes sphingosine-1-phosphate lyase 1 that catalyzes the final degradation step of sphingolipid that is involved in angiogenesis, vascular maturation, and immunity. Biallelic *SGPL1* pathogenic variants can cause significant glomerulopathy. Out of the 30 patients reported to have *SGPL1* pathogenic variants, 8 presented with CNS, while 4 had fetal demise [33–35]. The most significant extrarenal manifestation is primary adrenal insufficiency. Other extrarenal manifestations include ichthyosis, immunodeficiency, and neurological abnormalities including sensorineural hearing loss. A few other rare genetic causes of primary CNS have been described, such as ARHGDIA [36], MAGI2 [37], CRB2 [38], Lowe syndrome [39], and congenital disorders of glycosylation [40].

Secondary Nephrotic Syndromes

CNS may be secondary to some systemic diseases, including congenital or neonatal infections, and immune disorders.

Infections

Congenital syphilis has been known to cause CNS. The prevalence of CNS was 2.4% among neonates and infants with congenital syphilis in Thailand [41]. Neonates with syphilis usually present with nephrotic syndrome at 2–3 months of age, although presentation in the neonatal period may occur. Membranous nephropathy is a common biopsy finding. Antimicrobial therapy, usually penicillin, is curative if irreversible renal lesions have not developed [42].

Congenital cytomegalovirus infection, associated with certain strains of the virus, may be associated with CNS [43]. Neonatal CMV infections have also been reported to cause CNS [44]. Renal histology shows diffuse mesangial sclerosis, and patient respond satisfactorily to therapy with ganciclovir.

Toxoplasmosis has been associated with CNS, together with neurologic or ocular features [45]. In one report, a 3-month-old girl with CNS and toxoplasmosis responded well to spiramycin therapy [46]. Congenital rubella can cause CNS due to membranous glomerulonephritis [44]. While acquired immunodeficiency syndrome caused by the human immunodeficiency virus may be associated with nephropathy, including nephrotic syndrome that presents in older children, no patients with CNS caused by this infection has been reported [44, 47]. Hepatitis B virus commonly causes membranous nephropathy in children and adults, but has not been reported to cause CNS. Other infections that might be rarely associated with CNS include measles, pertussis, herpes simplex and herpes zoster.

Immune Disorders

Although systemic lupus erythematosus is rarely diagnosed before 5 years of age, an infantile form of the disease has been reported. Nephrotic syndrome was the major clinical finding in five infants aged 6 weeks to 6 months with systemic lupus erythematosus [48]. These patients had elevated antinuclear antibody titers, hypocomplementemia, and diffuse proliferative glomerulonephritis. Response to the immunosuppressive therapy was unsatisfactory.

Nephrotic syndrome due to membranous nephropathy has been observed antenatally in infants from mothers with mutations in the metallomembrane endopeptidase gene, which encodes the neutral endopeptidase (NEP) expressed on podocytes. During pregnancy, the fetal NEP protein induces a maternal alloimmune response, resulting in the production of maternal antibodies to fetal NEP protein. This in turn leads to glomerular subepithelial immune deposits in the fetus and neonate [49]. The infant presents with nephrotic syndrome, but with time the proteinuria decreases as the maternal antibodies and immune deposits decline. However, persistent proteinuria and chronic renal insufficiency may be observed due to nephron loss and renal scarring.

Diagnosis

Clinical Findings

A thorough evaluation of a newborn baby or small infant with suspected CNS is important (Table 1). Family history may reveal previous fetal or infant deaths, parental consanguinity, autoimmune diseases, or early-onset neurological or renal diseases. Antenatal history of hydrops fetalis, growth retardation, or maternal infections may be present. Most Finnish children with *NPHS1* mutations are born premature with mean birth weight of 2600 g. Placentas may be larger than normal. Amniotic fluid is often meconium stained, although most neonates do not have pulmonary problems.

Classical features of CNS include generalized edema, abdominal distension, and ascites. The degree of proteinuria varies and hence clinical signs of CNS may not be evident during the first weeks of life. Blood pressure levels may be low due to low oncotic pressure related to hypoproteinemia, or elevated if kidney impairment has developed. In severe forms of CNS, urinary protein >20 g/l, and serum albumin level <10 g/l is noted right after birth. The severity of proteinuria may only manifest after partial correction of hypoalbuminemia with albumin infusions. Microscopic hematuria or leukocyturia may be present. While oliguria is common, blood levels of creatinine and urea levels are variable. Most patients with *NPHS1* mutations have normal renal function in the first few months, whereas rapid deterioration of kidney function may occur in other genetic forms. Profound hyperlipidemia is often present in severe CNS. Complications associated with CNS include sepsis, thrombosis, and hypothyroidism.

Physical investigations should look for extrarenal manifestations that suggest genetic causes, including microcephaly (Galloway-Mowat

Table 1 Evaluation of an infant with suspected CNS

	Diagnosis	Primary form (genetic)	Secondary causes
History	Prenatal ultrasonography: kidney size, echogenicity Gestation (<37 weeks) Birth weight, height Large placenta Respiratory problems; meconium-stained amniotic fluid	Affected siblings Previous infant deaths, miscarriage in family Consanguinity (mostly recessive inheritance)	Congenital infections (fever with rash, cat exposure, serology, PCR) Maternal mutations in neutral endopeptidase (NEP)
Examination	Edema, ascites Cardiovascular exam Systemic infections Urine output	Extrarenal features (dysmorphic features; skeletal, neurological, cardiac, visual or hearing defects; genitalia)	Extrarenal features (rash, hepatosplenomegaly, cataract; cardiac or neurological abnormalities)
Urine, blood investigations	Urine protein to creatinine ratio, urinalysis Blood urea, creatinine, electrolytes, albumin, glucose, thyroxine, thyroid stimulating hormone, coagulation status, lipids	Gene panel: *NPHS1, WT1, NPHS2, LAMB2, PLCE1* Extended gene panel, exome sequencing (if needed) Karyotype (*WT1*) Adrenal function (*SGPL1*) Metabolic workup (mitochondriopathies)	Maternal serology Patient serology; blood DNA/RNA (syphilis, toxoplasmosis, CMV, rubella, measles, pertussis) Immunology: lupus serology; complement C3, C4; anti-NEP antibodies
Imaging (where appropriate)	Abdominal ultrasound (kidney size, echogenicity) Chest X-ray Doppler studies (if thrombosis suspected) Echocardiography	Brain imaging Skeletal imaging Pelvic ultrasound Echocardiography (*NPHS1, NPHS2,* mitochondrial disorders)	Brain imaging Skeletal imaging Echocardiography

syndrome), neurological disorders (Galloway-Mowat syndrome, *LAMB2*, *SGPL1,* mitochondriopathies), abnormalities of the genitourinary tracts (*WT1*), eye abnormalities (*LAMB2, SGPL1,* mitochondriopathies), sensorineural hearing loss (mitochondriopathies, *SGPL1*), and skeletal disorders (nail-patella syndrome) [6]. In low-resource settings where genetic testing is not available, clinicians may consider pelvic ultrasound scans and chromosomal karyotyping in infants with complete female or ambiguous genitalia to look for male pseudohermaphroditism (Denys-Drash syndrome). Karyotyping is also useful in patients with confirmed *WT1* mutation to assess gonadal malignancy risks. Cardiac structural defects are rare, but ventricular hypertrophy may be present. Patients with *NPHS1*, *NPHS2*, and *PLCE1* genetic defects do not have extrarenal malformations. Clinicians should assess for signs of congenital infections like rash or cutaneous scars, cardiac anomalies, hepatosplenomegaly or jaundice, eye defects, and neurological or skeletal abnormalities. If congenital infections are suspected, a search for specific antibodies, or bacterial or viral DNA/RNA by polymerase chain reaction is required (Table 1).

Kidney Biopsy

A variety of histopathological changes can be found in CNS, such as minimal change disease with or without mesangial expansion, FSGS, and diffuse mesangial sclerosis. Nonspecific tubulointerstitial changes such as tubular dilatation, interstitial fibrosis, and inflammation may be seen, as in many proteinuric diseases. Renal histological changes do not correlate with genotypes. If the genetic diagnosis is apparent based on clinical features (ambiguous genitalia suggesting *WT1,* or eye anomalies suggesting *LAMB2* defects), or if genetic testing has been or will be performed promptly, then the kidney biopsy may not be necessary at initial diagnosis. The biopsy may help provide information on the presence and extent of glomerular sclerosis and interstitial fibrosis, and might impact treatment strategies. On the other hand, in the interpretation of sclerosis or fibrosis in renal biopsies, clinicians should be wary of errors due to focal sampling.

Genetic Testing

Genetic testing is preferred for the definitive diagnosis of primary CNS. Analysis of *NPHS1*, *NPHS2, WT1*, *LAMB2*, or *PLCE1* mutations uncovers the genetic etiology in >80% of cases, and is warranted in all patients [6, 50]. If this analysis is negative, a more comprehensive screening using either an expanded gene panel (for other genes implicated in nephrotic syndrome) or whole exome sequencing is recommended as it provides the genetic diagnosis in another ~5% cases [6, 15, 51]. This general strategy, however, should be tailored according to the clinical assessment, resource availability, and population-specific considerations. Prenatal genetic diagnosis may be considered in families with a known risk for CNS and rapid turnaround time for the genetic results is possible if the genetic variant is already known.

Knowledge of the etiology helps in management and prognostication. Immunosuppressive therapy should be avoided in patients with a genetic diagnosis; progression to ESKD is also rapid in genetic compared to non-genetic cases. Surveillance and follow-up for extrarenal manifestations can be more targeted with a genetic diagnosis (e.g., endocrine or oncological features in *WT1* or *SGPL1* cases). Genetic testing also enables genetic counseling for the family.

Management

The goals of therapy are to provide good nutrition for optimal weight gain, control edema, and prevent complications like thrombosis, infections, and hemodynamic instability. Since 1970, these goals were achieved in the first months by daily albumin infusions and provision of sufficient nutrition. The ultimate aim is to allow the child to reach a body weight at which preemptive bilateral nephrectomy and dialysis may be performed, followed by transplantation at 1–3 years of age. This “aggressive” approach has been used by many units and resulted in improved survival of children with CNS [52, 53].

However, at least 55% of patients with CNS do not reach ESKD by the age of 2 years, and hence a more conservative and individualized treatment strategy has been recommended by the European Society of Pediatric Nephrology [54]. This protocol, tailored according to the clinical severity of nephrotic syndrome, its complications, as well as response to therapy with ACEi and prostaglandin synthesis inhibitor, has emphasized the possibility of ambulatory care management.

A summary of current management strategies is provided in Table 2.

Albumin Substitution

Since CNS is a heterogeneous group of disorders, urinary protein loss is variable (2–150 g/l), with varying clinical status of the patients. Infants with lower urinary protein losses may have little or no edema, and no albumin replacement may be needed. On the other hand, CNS infants with heavy and prolonged proteinuria are usually critically ill with anasarca, intravascular hypovolemia (slow capillary refill, low blood pressure and /or tachycardia), and often septicemia. Persistent heavy proteinuria can also lead to complications like reduced growth, thrombosis, and infections. While albumin substitutions only temporarily correct hypoproteinemia in patients with heavy urinary losses, it allows control of severe edema and its related complications. Hence, in such cases, protein substitution by albumin or plasma is mandatory.

The decisions on administration of albumin infusions should be based on clinical status instead of target serum albumin levels. After acute resuscitation, albumin infusions should be given together with furosemide. Initially, 20% albumin substitutions may be divided into three infusions a day, starting dose 0.2–1 g/kg (1–5 ml/kg) per infusion, each over 2 h. One to two boluses of

Table 2 Summary of management strategies in children with CNS

Nutrition and fluids
Avoid unnecessary intravenous fluids and salt supplements in stable patients
Adequate nutrition: Calories 120–150 Cal/kg/day; protein 3–4 g/kg/day
Nasogastric tube or gastrostomy often required for proper feeding
Adjust nutrition with declining kidney function
Multivitamins; calcium, magnesium, and potassium supplements may be required
Albumin infusions
Albumin infusions are indicated in unstable patients (severe edema with complications)
Initial 20% albumin dose 0.2–1 g/kg, up to three infusions a day, each over 2 h
Maintenance 20% albumin dose is 1–4 g/kg/day (over 6 h; at night)
During albumin infusion, 1–2 doses of furosemide 0.5–2 mg/kg are given
Medications
Angiotensin converting enzyme inhibitors, angiotensin II type 1 receptor antagonists
After neonatal period: captopril 0.01–0.5 mg/kg twice daily; increase dose gradually
Indomethacin is usually not effective
Anticoagulation prophylaxis, especially with deep vein catheters
Warfarin or enoxaparin
Antithrombin III infusion (50 IU/kg) prior to invasive procedures
Thyroxine substitution, dosed according to thyroxine stimulating hormone levels
Parenteral antibiotics if systemic bacterial infection is suspected
Intravenous immunoglobulin considered in recurrent severe infections
Nephrectomy
Unilateral nephrectomy in selected cases to reduce proteinuria
Routine preemptive nephrectomy is not necessary in stable patients
Consider preemptive bilateral nephrectomy in refractory severe nephrotic state with complications that are difficult to manage (repeated infections, undernutrition and development delay, thrombosis, hemodynamic instability)
Before transplant: Consider bilateral nephrectomy if persistent and significant nephrotic state
Renal replacement therapy
Indication for dialysis: ESKD or after bilateral nephrectomy
Peritoneal dialysis preferred; hemodialysis if peritoneal dialysis contraindicated, or caregiver preference
Transplantation
May be preemptive, provided nephrotic state has resolved
Extraperitoneal grafting is preferred
In autosomal recessive conditions, parents (heterozygous carriers) are suitable donors

intravenous furosemide (0.5–2 mg/kg) are given with each albumin infusion. After few weeks, 20% albumin is given as one infusion (~3–4 g/kg, 15–20 ml/kg) over 6–8 h during the night, allowing for home care during the daytime [9]. Additional furosemide boluses are given during the daytime when the maximum albumin dosing of 4 g/kg/day has been reached. In very edematous patients, IV furosemide is preferred (2–10 mg/kg/day), but in more stable patients, the medication is given orally (2–4 mg/kg/day) [54]. In patients not receiving albumin infusions, diuretics may be given to improve fluid control while exercising caution to avoid intravascular volume depletion.

Management with albumin substitutions should be tailored to the individual patient, and treatment strategies may change within the same patient over time. In some patients, urinary protein losses eventually decline, even in the absence of kidney impairment, resulting in clinical improvement and enabling discontinuation of albumin infusions. This occurred in three of seven CNS children by the age of 10 weeks to 9 months in a single-center study [55]. In a French survey, out of 53 patients, albumin infusions were withdrawn in 10 patients (18%) who had normal eGFR at a median age of 11 (range 5–29) months [56]. Clinicians therefore should exercise clinical judgment when ordering albumin infusions, balancing between the need to avoid intravascular hypovolemia and severe edema with its related complications, versus the need to avoid excessive or unnecessary albumin infusions especially in patients who show clinical improvement and decline in urinary protein losses with time. Albumin infusions can lead to increased costs, prolonged hospitalizations, and need for a central venous catheter with attendant risks of thrombosis and jeopardizing future hemodialysis access.

Home albumin programs have been implemented in some centers [55]. In a report from 17 tertiary units in Europe, out of 68 CNS children, 14 (20%) from 5 centers received albumin infusions at home [57].

Antiproteinuric Medications

In primary CNS, renin–angiotensin–aldosterone system blockade may reduce proteinuria by decreasing glomerular perfusion pressure. Additionally, it possibly also exerts a protective effect on the podocytes and slow renal failure progression. The benefit of ACEi in primary CNS is based on small single-center or retrospective studies. In a recent multicenter survey, 70% (23/33) of CNS children treated with an ACEi had a significant increase in their serum albumin by 3–8 g/l, and a significant reduction of weekly albumin infusion dose by 0–4 g/kg/week, although the latter was not significant among patients without *NPHS1* mutations [57, 58]. The type of *NPHS1* genetic variant (truncating/ frameshift/ splice site versus missense) did not correlate with the response to ACEi. The first anti-proteinuric drug of choice is captopril, because of shorter half-life and hence safer dose titration. It can be commenced after the neonatal period, and the dose should be increased gradually (maximal daily dose in infants <3 months of age is 2 mg/kg, and in older infants 6 mg/kg) [54]. Frequent monitoring of proteinuria, urine output, and kidney function is important. Angiotensin II type 1 receptor antagonists may be used in place of ACEi, but not in combination with ACEi due to increased risk of adverse effects.

Sole treatment with captopril and indomethacin has been reported to cause prolonged and sustained clinical remission in infants with primary CNS [59]. However, opinions differ on whether indomethacin (1–5 mg/kg/day) should be added to ACEi in refractory cases. There were no differences in serum albumin levels or albumin infusion requirements between children on ACEi only versus those on ACEi and indomethacin [57].

Nutrition

Traditionally, infants with severe CNS are given high caloric (120–150 kcal/kg per day) and protein (3–4 g/kg per day) intake [52]. The addition of a whey- and casein-based protein product, glucose polymers, and/or fat emulsions to breast milk or cow milk formulae is required. At weaning, a low-salt diet is ensured. Most patients require a nasogastric tube or gastrostomy to ensure adequate nutritional intake. A complete multivitamin preparation can be given according to the recommended dietary allowances for healthy children of the same age. The daily fluid intake should not be restricted, in order to ensure adequate nutritional intake in infants and to avoid intravascular volume depletion. Nevertheless, if the kidney function deteriorates, modification to this regime should be made.

Additional Medications

In addition to albumin, many other proteins are lost into urine. These include thyroid binding globulin, plasminogen, antithrombin III (ATIII), immunoglobulin G, transferrin, vitamin D binding protein, apoproteins, lipoprotein lipase, and ceruloplasmin [52]. Hypothyroidism, thrombotic events, bacterial infections, anemia, and bone mineral disorders are common. Patients should receive vitamin D3 (10–40 μg/day) and alphacalcidiol (0.1–0.3 μg/day) when parathyroid hormone level is increased. Supplementary magnesium (50 mg/day) and calcium (500–1000 mg/day) are given to ensure normal serum levels. Patients with CNS often have low serum thyroid-binding globulin and thyroxine levels. It is necessary to treat these patients with thyroxine, adjusted according to thyroxin stimulating hormone levels, which remain normal initially and increase during the first months [52].

Urinary excretion of plasminogen and ATIII leads to compensatory protein synthesis, resulting in increased levels of macroglobulins, fibrinogen, thromboplastin, and factors II, V, VII, X, and XII, contributing to hypercoagulopathy. Thromboses and severe coagulation problems have been reported in children with CNS. Administration of warfarin to patients with central catheters has decreased the incidence of severe thrombotic events. Before surgical or vascular procedures, warfarin is stopped and ATIII (50 IU/kg) is given 1 h before the procedure to temporarily correct the ATIII deficiency. Besides warfarin, enoxaparin has been prophylactically used in CNS infants [60]. Urinary loss of transferrin, transcobalamin, and erythropoietin can result in anemia [61]. This can be managed with erythropoietin up to 500 IU/kg/dose, although it may be ineffective in some patients resulting in the need for repeated blood transfusions. On the other hand, some patients with CNS have thrombophilia necessitating the use of low-dose aspirin.

Bacterial infections may be a major problem in CNS. Urinary loss of immunoglobulins and complement factors B and D can lead to increased susceptibility to infections by encapsulated bacteria such as pneumococci. Catheter-related sepsis is common. Infection rates may be 2.4–3 episodes per patient per year, and these are not decreased by prophylactic antibiotics or intravenous immunoglobulins (IVIg), nor increased by the use of central venous catheters [56, 62]. While prophylactic antibiotics are not recommended, prophylactic IVIg may be given to patients with recurrent severe infections and/or low plasma levels of immunoglobulin G. A high index of suspicion remains crucial, especially since symptoms are vague and nonspecific, and plasma levels of C-reactive protein can remain low due to urinary losses. Antibiotic therapy should be started promptly at initial suspicion, and should be broad-spectrum to target nosocomial infections. Response to treatment is satisfactory. Vaccinations should be given as per schedule, including against encapsulated bacteria and varicella. Annual influenza vaccines should be given.

Primary CNS, being genetic in most cases, usually does not respond to immunosuppressive agents like prednisolone or calcineurin inhibitors. Accordingly, only one of 45 patients with CNS and no known genetic defect achieved prolonged remission with steroid therapy [3]. There are few case reports of patients with pathogenic variants in *WT1* and *PLCE1* who show improvement in proteinuria after immunosuppressive therapy [26, 63]. While the mechanism is not clear, there is data to suggest direct effects of immunosuppressive medications on the podocytes [64]. In CNS infants with no identified genetic defects, a trial with steroids or calcineurin inhibitors has been suggested [54]. In patients with CoQ10-related genetic defects, CoQ10 supplementation may decrease proteinuria and slow CKD progression [31, 32]. In secondary CNS due to infections, specific therapy against the infectious agent is often effective.

Nephrectomy and Dialysis

Unilateral nephrectomy, together with ACEi and indomethacin, may be performed to reduce urinary protein losses in infants with CNS [65], so as to decrease the requirement of albumin infusions. According to a recent report, unilateral nephrectomy decreased albumin dose by 5 g/kg/week and increased plasma albumin levels by 4 g/l, but increased serum creatinine from 21 μmol/l to 45 μmol/l [57].

In patients who develop complications associated with the nephrotic state (infections, thromboses, unstable hemodynamics) despite conservative therapy, an “aggressive” approach may be considered. This involved preemptive bilateral nephrectomy followed by peritoneal dialysis or hemodialysis when an infant is 7–10 kg. During dialysis, the general condition improves, with catch-up growth and increase in muscle mass [66]. This allows improvement of the hypoproteinemic, prothrombotic, and malnourished state before kidney transplantation is performed a few months later.

In stable infants with no complications, a conservative approach should be considered. This involves no preemptive nephrectomy before the development of ESKD, so as to delay initiation of renal replacement therapy [67]. In a recent multicenter study, the timing of renal replacement therapy did not influence the survival and growth in children with CNS due to *NPHS1* genetic defects [68]. Peritoneal dialysis is the modality of choice in patients with CNS, but one-third can switch to hemodialysis [58]. Infants with CNS have comparable dialysis outcomes to infants with other renal diseases. The 5-years patient and graft survivals are excellent and comparable to patients with congenital structural anomalies of the kidney and urinary tracts [58].

In Denys-Drash syndrome, progression to ESKD is rapid. Because of the significant risk of Wilms tumor, prophylactic bilateral nephrectomy is performed after onset of dialysis. If nephrectomy has not been performed, tumor surveillance with abdominal ultrasound should be performed every 3 months.

Kidney Transplantation

Renal transplantation is the curative therapy for most patients with CNS, and is often performed at 1–3 years of age using adult-size kidneys. Size discrepancy and the risk of thrombotic complications make this a surgically challenging procedure. Prior to transplantation, it is imperative that the patient does not have the nephrotic state with normal serum albumin levels (hence no longer prothrombotic), in order to minimize risks of thrombosis in the graft.

Recurrence of nephrotic syndrome in the graft is exceptional but has been reported in patients with CNF, who develop anti-nephrin antibodies after transplantation. Treatment of recurrence with cyclophosphamide and plasmapheresis and, more recently, with anti-CD20 antibodies normally leads to remission [69]. Overall, the outcomes of kidney transplantation in CNS are good and comparable to other underlying renal conditions [56, 57, 70]. Additionally, most patients achieved good quality of life and have normal schooling [71]. Patients, who were transplanted as infants, have normal growth and pubertal development, but males may have reduced fertility in adulthood [72]. Chronic allograft nephropathy is a major problem and second transplantations are often needed by young adulthood [68, 70].

Abstract

Steroid-resistant nephrotic syndrome (SRNS) is a paradigmatic disease to illustrate the major clinical consequences that can arise from genetic testing. Patients with pathogenic variants should be spared inefficient and potentially toxic immunosuppressive therapy; although a partial reduction of proteinuria has been reported with calcineurin inhibitors and/or renin-angiotensin-aldosterone inhibitors in a small number of cases. A better understanding of disease mechanisms may help identifying targeted therapeutic agents, and guide specific management of extra-renal features. Moreover, these patients have a very low risk of recurrence after kidney transplantation. Finally, such diagnosis is crucial for genetic counseling with respect to family planning but also to assess the suitability of relatives as organ donors. Next-generation sequencing approaches are increasingly used as the first step of genetic analyses. Causative pathogenic variants are identified in approximately 30% of children with SRNS and at least 66% in congenital and infantile cases. Among these genes, *NPHS1* and *NPHS2* are by far the two main autosomal recessive genes implicated in SRNS, while *INF2* is the leading cause of autosomal dominant SRNS. Most novel gene variants are rare and involve few families. Moreover, NGS has revealed causative variants in unexpected genes such as ciliary or tubular genes and has widened the phenotypes associated with SRNS. More complex inheritance involving susceptibility variants, oligogenism or interallelic influence of variants have also been described as a cause of SRNS.

Introduction

Over the past decades, genetic research aimed at unraveling the causes of Mendelian forms of steroid-resistant nephrotic syndrome (SRNS) has led to the description of new pathologies, all of which have in common a primary dysfunction of the podocyte, and are grouped under the term of "hereditary podocytopathies." The classification of these pathologies has become more complicated as variants in new genes have been identified. Indeed, since the discovery of *NPHS1* coding for nephrin in 1998 by Kestila et al. [1], and *NPHS2* coding for podocin in 2000 by Antignac et al. [2], more than 60 genes whose mutations are responsible for SRNS have been discovered (Table 1). The first genes identified appeared to be specific for certain clinical entities such as *NPHS1* whose biallelic pathogenic variants are the main cause of congenital nephrotic syndrome [1], *NPHS2* whose biallelic pathogenic variants have been identified in childhood-onset autosomal recessive (AR)-SRNS [2], or *ACTN4* whose monoallelic pathogenic variants lead to late-onset SRNS or proteinuria with focal segmental glomerulosclerosis (FSGS) [3]. However, subsequent studies have shown, for instance, that *NPHS2* biallelic pathogenic variants could lead to congenital nephrotic syndrome [4], and conversely that less severe *NPHS1* variants were responsible for SRNS beginning in childhood [5]. Thus, hereditary podocytopathies are a

Table 1 Genes implicated in hereditary SRNS and FSGS and associated phenotypes

Gene	Transmission	Encoded protein	Typical histology	Extra-renal involvement; comments
Autosomal recessive isolated SRNS				
NPHS1 [1]	AR	Nephrin	MCD, FSGS	–

continuum of disorders characterized by glomerular proteinuria of variable severity.

They share common features with the most prevalent immune-mediated forms of idiopathic nephrotic syndrome. Apart from the rare congenital forms, the initial presentation of immune-mediated and hereditary SRNS is generally similar with albuminuria, hypoalbuminemia and edema, and minimal change disease (MCD) or FSGS on biopsy with podocyte foot process effacement by electron microscopy. Family history, multi-drug resistance, progression to kidney failure, and lack of recurrence after kidney transplantation suggest a genetic origin. Indeed, in hereditary forms of SRNS and unlike immune-mediated ones, the protein loss is caused by structural defects of the podocyte, which are not expected to be sensitive to immunosuppressive drugs and are corrected after transplantation.

Next-generation sequencing (NGS) approaches have wholly modified the diagnosis screening algorithms and are recommended as the first step in genetic testing [6–9]. Pathogenic variants are now identified in approximately 30% of children with SRNS [6, 10]; and at least 66% of the cases presenting before 1 year of age [6, 11]. Among these genes, *NPHS1* and *NPHS2* are by far the two main genes implicated in SRNS [6, 10] in European populations, while *COQ8B* (previously *ADCK4*)-mitochondriopathy is frequent in Asia and *APOL1*-related disease in patients of African descent. Further details regarding geographical distribution are provided in chapter "Genetic Aspects of SRNS." Most novel gene variants are rare and involve few families. Moreover, NGS has revealed causative variants in unexpected genes such as ciliary or tubular genes and has widened the phenotypes associated with podocyte gene mutations.

This chapter presents an overview of the clinical features of the main hereditary SRNS, including syndromic forms and advances in the study of familial forms of steroid-sensitive nephrotic syndrome (SSNS), but excluding mitochondriopathies such as the potentially treatable CoQ10-related disorders like late-onset *COQ8B*-associated SRNS that are described in chapter "Mitochondriopathies." Treatment principles, transplant outcomes, and rare cases of recurrence are also discussed. Molecular genetics are detailed in chapter "Genetic Aspects of SRNS."

Isolated SRNS

Autosomal Recessive Forms

NPHS2

NPHS2 biallelic pathogenic variants (Online Mendelian Inheritance in Man, OMIM database identifier#600995) are the main genetic cause of SRNS beginning after 1 month of age and are responsible for 30–40% of AR-SRNS and 10% of sporadic cases [12–15]. The mean age at onset of NS ranges from 2.6 to 3.4 years of age [4, 13] and kidney histology displays MCD or FSGS [2, 16, 17]. Weber et al. found that frameshift or nonsense biallelic variants cause an earlier onset of SRNS than missense variants [13]. In addition, children with the p.Arg138Gln biallelic variant present with early-onset disease [4, 13]. At least two variants, p.Val180Met and p.Arg238Ser are associated with a milder phenotype, including later age at onset of SRNS and at kidney failure [13]. The p.Arg138* variant has been associated with a high incidence of cardiac abnormalities in children [18], although this finding has not been confirmed in patients carrying other variants [19]. Cardiac ultrasound is recommended in the initial evaluation of these children. Most variants cause retention of the mutated protein in the endoplasmic reticulum [20, 21], such as the most prevalent p.Arg138Gln variant representing 32% of the mutated alleles in patients of European descent [13, 20, 22, 23]. Variants that result in podocin endoplasmic reticulum-retention are often associated with earlier SRNS than variants that allow membrane targeting of podocin [4, 20]. This paves the way to chemical chaperones as promising specific therapies to properly target the mutant podocin to the slit diaphragm with the aim of reducing the severity of the SRNS [23].

In addition, *NPHS2* biallelic pathogenic variants have been found in 15–39% of infants with congenital nephrotic syndrome [11, 17, 24], making it the second most common cause of congenital nephrotic syndrome after *NPHS1* variants. The phenotype of these children is less severe than with *NPHS1* variants with a median age at onset of 29 days vs. 2 days, and slower deterioration of kidney function [17].

Moreover, a 2.77-fold increased risk of developing microalbuminuria has been demonstrated in adults bearing the p.Arg229Gln *NPHS2* polymorphism [25]. This non-neutral variant thought to decrease the affinity of podocin for nephrin [26] is present in 3% of the general population with large inter-ethnic variability (7% in Finnish, 0.01% in East-Asian subjects). It has been shown that the association of the p.Arg229Gln variant on one allele with a *NPHS2* pathogenic variant on the other allele induces SRNS that generally occurs later and evolves more slowly than in patients with two pathogenic *NPHS2* variants [6, 14, 26–31]. This association accounts for most cases beginning in adulthood [27, 31]. However, Tory et al. demonstrated that the p.Arg229Gln variant is only pathogenic when associated to C-term variants (exons 7–8) on the second allele [32] through altered podocin dimerization and retention in the endoplasmic reticulum [33]. Therefore, the disease is not transmitted according to a “classical” mendelian autosomal recessive model and genetic counselling is complex [32]. Clinicians must be aware that a [p.Arg229Gln][N-terminal variant] genotype or biallelic p.Arg229Gln variants do not explain the SRNS that may be immune-mediated and therefore may respond to intensified immunosuppression or recur after transplantation [32, 34].

NPHS1

NPHS1 (OMIM#602716) encoding nephrin has been identified as the major gene involved in congenital nephrotic syndrome of the Finnish type (CNF) [1] extensively described in ▶ Chap. 11, “Congenital Nephrotic Syndrome.” However, later findings have broadened the spectrum of renal disease related to *NPHS1* variants since patients with childhood-onset and even adult-onset SRNS may rarely carry *NPHS1* biallelic pathogenic variants [5, 35]. Indeed, the p. Arg1160* biallelic variant may result in a milder phenotype in about 50% of cases with histologic findings consistent with CNF and either mild proteinuria or complete remission up to 19 years of age [17, 24]. Thereafter, Antignac group identified *NPHS1* variants in 10/160 patients (142 families) presenting with SRNS at a mean age of 3 years (0.5–8), and MCD/FSGS lesions [5]. Affected children were compound heterozygous for at least one “mild” missense variant, which exhibited normal trafficking of nephrin to the plasma membrane and maintained its abilities to form homodimers and to heterodimerize with NEPH1. These findings explain the lesser severity of disease observed in these cases.

PLCE1

Hinkes et al. identified *PLCE1* biallelic variants (OMIM#610725) in children with either DMS and early-onset SRNS (median age at diagnosis 0.8 years and kidney failure before 5 years, or FSGS and a later onset of SRNS (2–8 years) [36]. Subsequently, Gbadegesin, from the same group, showed that *PLCE1* truncating variants accounted for 28.6% of cases of isolated DMS in a cohort of 40 patients from 35 families mostly of Turkish origin [37]. An earlier age of onset is reported in patients with *PLCE1* splice-site variants compared with C-terminal truncating variants or missense variants [6]. Interestingly in the original description, two patients bearing truncating variants achieved complete remission when treated early and remained free of proteinuria after several years of follow-up [36]. Later, four families with transiently affected or even asymptomatic family members – although homozygous for truncating mutations – have been published, suggesting an incomplete penetrance of *PLCE1*-associated SRNS [38], an uncommon phenomenon in AR-diseases. A second-locus modifier, yet to be identified, could explain this phenomenon, although variants in 19 candidate genes including 16 phospholipases were ruled out [38]. The reported incomplete penetrance is consistent with the lack of renal phenotype observed in $Plce1^{-/-}$ mice [36].

Less Common Gene Defects Causing AR-SRNS

MYO1E

Mele et al. identified a *MYO1E* biallelic missense variant (OMIM#614131) in a consanguineous family with SRNS, then a truncating variant in 1/29 families with a similar phenotype [39]. The five patients developed SRNS between the ages of 6 and 18 years, and those who had been biopsied had FSGS. In addition, the electron microscopy revealed a thickening and disorganization of the glomerular basement membrane and mesangial matrix expansion. These lesions were very similar to those of *myo1e* knock-out mice. The patients had SRNS but a partial response to cyclosporin.

PTPRO

PTPRO biallelic pathogenic variants (OMIM#600579) were identified by Ozaltin's group in two Turkish consanguineous families [40]. The five affected siblings had developed nephrotic-range proteinuria and 2 had overt-SRNS between the ages of 5 and 14 years with MCD/FSGS and severe foot process effacement, and one progressed to kidney failure at the age of 18 years. Unexpectedly, one 9-year-old child had initial steroid-sensitivity and steroid-dependence with prolonged remission on oral cyclophosphamide and secondary steroid-resistance. Three additional children also presented partial remission with intensified immunosuppression and renin-angiotensin-aldosterone inhibitors (RAASi).

CRB2

Biallelic *CRB2* variants (OMIM#609720) have been identified in four families with isolated SRNS with FSGS diagnosed between 9 months and 6 years of age [41]. Of note, *CRB2* mutations were also detected in five fetuses and one infant with cerebral ventriculomegaly and echogenic kidneys with histopathological findings of congenital nephrosis [42] (▶ Chap. 11, "Congenital Nephrotic Syndrome").

CD2AP

Although a dominant inheritance of *CD2AP* variants (OMIM#604241) was first suggested by mouse models [43], subsequent data provided conclusive evidence that biallelic loss-of-function variants causes childhood-onset SRNS with FSGS in humans [44, 45].

Autosomal Dominant Forms

INF2

Pollak's group identified monoallelic pathogenic variants in the *INF2* gene (OMIM#610982) encoding the inverted formin 2 in 12% of autosomal dominant (AD)-FSGS families [46]. Subsequent studies confirmed that *INF2* variants are the most common cause of AD-FSGS [47–49]. Age at onset of proteinuria ranges from 5 to 72 years and at kidney failure from 13 to 70 years. As expected for AD-diseases, incomplete penetrance was also reported by most authors and some individuals presented with only mild to moderate proteinuria. Conversely, variants in this gene seem to be responsible for <1% of sporadic cases of FSGS due to de novo variants [47–49]. Boyer et al. later demonstrated that *INF2* variants are the main cause of Charcot-Marie-Tooth disease with FSGS (see below) [50]. Most cases of *INF2*-related SRNS have MCD/FSGS on kidney biopsy, although there are some reports of other changes such as IgA nephropathy (a fortuitous association is suspected) [51], or thrombotic microangiopathy in individuals also bearing the atypical hemolytic uremic syndrome CFH-H3 haplotype, this co-inheritance being the most likely explanation for this unusual presentation [52]. No post-transplant recurrence has been reported in patients with *INF2* variants.

TRPC6

Following the first description of a *TRPC6* monoallelic pathogenic variant by Winn's group in a large kindred from New Zealand [53], *TRPC6* variants were evaluated to be responsible for approximately 2–5% of AD-FSGS (OMIM#603965) [54–56]. Affected cases present with nephrotic-range proteinuria in their third or fourth decade with FSGS lesions and develop progressive kidney failure within 10 years after onset. *TRPC6* variants, mostly de novo, have subsequently been reported in children as young as 1 year old. Most of the patients have FSGS lesions although in a small group of patients, diverse biopsy findings such as MCD, C1q nephropathy, IgA nephropathy, and non-specific immune complex changes have been reported [57–60]. It is unclear whether the immune complex depositions are primary or secondary changes due to underlying podocyte injury because of the mutations. Notably *TRPC6* variants have been described in six children, one of whom was a 2-year-old boy with collapsing FSGS and rapid progression to ESKD due to a de novo variant [54, 55, 57, 58]. FSGS due to *TRPC6* variants is not associated with recurrence of disease following kidney transplantation.

WT1

A *WT1* disorder is characterized by congenital/infantile, childhood, or adolescent-onset of a progressive glomerulopathy that does not respond to steroids. Persistent proteinuria is present in the vast majority of cases (>95%), while criteria for diagnosis of SRNS may not be met initially [61–63]. Almost half of the reported patients present initially as an isolated proteinuria, although detailed examination following molecular diagnosis, detect additional findings including disorders of testicular development in majority of 46,XY individuals (for details see below). Accordingly, karyotype analysis is recommended in all prepubertal phenotypic females having a *WT1* diagnosis, despite lack of detectable abnormalities of the external genitalia and/or müllerian structures [7, 62, 64]. Surveillance for Wilms tumor is also recommended as SRNS can precede the tumor by as much as 4 years, be present at the time of tumor diagnosis, or develop years after completion of chemotherapy for the malignancy [62, 65]. The penetrance for WT is estimated to be ~40% in case of exonic variants, i.e., one tumor per 9 years at risk [61]. Therefore, it is important to screen all patients with ultrasonography of the urinary tract every 3 months until the age of 7 years [62, 64]. On the other hand, a few asymptomatic parents heterozygous for the same germline *WT1* variant in their affected offspring have been reported [61, 62, 66].

ACTN4

ACTN4 monoallelic pathogenic variants were the first cause of non-syndromic AD-FSGS identified by the Pollak group [3, 67]. Affected cases present with proteinuria starting in the teenage years or later, show FSGS, and slowly progress to kidney failure in the fifth decade of life, although earlier cases have been seldom reported [3, 68, 69]. Distinctive cytoplasmic electron-dense aggregates in podocytes were described in one study [70] but not confirmed by others. Overall, *ACTN4* variants seem to account for 3–4% of all non-syndromic AD-FSGS. Disease due to *ACTN4* variant is incompletely penetrant and obligate heterozygotes have been reported in multiple kindreds. Recurrence of disease in transplanted kidney in patients with FSGS due to *ACTN4* mutations have not been reported.

Less Common Gene Defects Causing AD-SRNS

ARHGAP24

A loss-of-function *ARHGAP24* variant was identified in one of 310 sequenced families with AD-FSGS [71]. The mother had died of kidney failure at 29 years of age, and 2 offsprings had reached kidney failure at 12 and 20 years of age, respectively. This mutation involved the conserved GAP-catalytic domain of the encoded actin-regulating protein Rho-GAP24 (OMIM#610586).

ANLN

More recently, Gbadegesin et al. identified variants in the *ANLN* gene (OMIM#616027) encoding the actin-binding protein anillin in two families with AD-FSGS [72]. Patients' phenotype was similar to that of other AD-SRNS with age at proteinuria onset varying from 9 to 69 years, FSGS on biopsies and ESKD occurring between 35 and 75 years and no post-transplant recurrence.

X-Linked Forms

TBC1D8B

Dorval et al. identified two different *TBC1D8B* hemizygous missense variants in two unrelated pedigrees with boys affected with early-onset SRNS and FSGS, whereas the mothers and a sister bearing the same variant had no or milder symptoms [73]. This is the first description of an X-linked SRNS.

Syndromic SRNS

SRNS and Urogenital Abnormalities

While various combinations of renal and other findings associated with a *WT1* pathogenic variant were designated as certain syndromes in the past, those designations are now recognized to be part of a phenotypic continuum and are no longer clinically helpful [62]. These include Denys-Drash syndrome (OMIM#194070), Frasier syndrome (OMIM #136680), Meacham syndrome (OMIM#608978), WAGR syndrome (OMIM#194072), isolated nephrotic syndrome type 4 (OMIM#256370), and hereditary Wilms tumor (OMIM#194070). Below the description of the two most common "classical" syndromes belonging to *WT1*-spectrum are nonetheless provided, for the ease of the reader. One should remember, however, that *WT1*-associated disorder presents with incomplete penetrance and variable expressivity. The most common additional findings include disorders of testicular development (with or without abnormalities of the external genitalia and/or müllerian structures) and Wilms tumor, while less common are congenital anomalies of the kidney and urinary tract (CAKUT) and gonadoblastoma.

Denys–Drash syndrome (DDS)

Denys–Drash syndrome (DDS)(OMIM#194080) was originally described as nephrotic syndrome associated with DMS, manifesting within the first year of life [74], predisposition to Wilms tumor and disorders of sex development [61, 62]. Glomerulopathy presents as infantile SRNS with DMS that progresses to kidney failure before 2–3 years of age [61, 63] and is frequently associated to hypertension [75]. Affected patients have a high risk of developing Wilms tumor, either unilateral or bilateral synchronous and/or metachronous, especially in patients with truncating variants [61, 65]. The median age at presentation of the tumor in DDS is 12.5 months, which is younger than in isolated Wilms tumor. Bilateral nephrectomy is recommended at the time of kidney transplantation because the risk of developing the tumor in residual renal tissue is very high. CAKUT are observed in about 10% of individuals with a *WT1* disorder [61, 63, 65]. The most common kidney abnormalities are duplex kidney, horseshoe kidney, and kidney malrotation. The most commonly reported urinary tract anomalies are vesicoureteric reflux, ureteropelvic junction stenosis, and urogenital sinus [62]. 46,XY children typically present with ambiguous or female external genitalia, gonadal dysgenesis, and a predisposition to the development of gonadoblastoma. Nonetheless, few 46,XY fertile males having a *WT1* pathogenic variant have been reported [62]. Patients presenting 46,XY disorder of testicular development (either a disorder of sex development or complete gonadal dysgenesis) should be consented for gonadoblastoma surveillance including prophylactic gonadectomies. 46, XX girls have normal ovaries, normal external genitalia, and are fertile; only two cases of complete gonadal dysgenesis are reported [62].

Frasier Syndrome

Frasier syndrome (OMIM#136680) is classically referred to in a case of late-onset SRNS in a 46, XY individual with complete gonadal dysgenesis and gonadoblastoma [76]. At molecular level, two distinct single-nucleotide variants in the splice donor site of intron 9 of *WT1* gene that change the ratio of +KTS/-KTS isoforms are typically detected. Patients with Frasier syndrome exhibit milder phenotypes with nephropathy onset at adolescence [77]. It is characterized by progressive SRNS with FSGS [61, 63, 78, 79]. Primary amenorrhea, hypergonadotrophic hypogonadism, and streak gonads are associated with a high risk of gonadoblastoma. Management requires a multidisciplinary team, including a geneticist, endocrinologist, urologist, and psychologist. Prophylactic gonadectomy is recommended. Rarely, the KTS mutation in a 46,XY individual may result in disorder of sex differentiation clinically presenting as ambiguous genitalia, extremely high gonadotropin levels, delayed adrenarche, and para-testicular leiomyoma without gonadal dysgenesis [80].

SRNS and Ocular Abnormalities

Pierson Syndrome

Pierson syndrome (OMIM#609049) is a rare AR-disorder involving the basement membrane caused by biallelic variants in *LAMB2*, encoding laminin β2, and characterized by congenital nephrotic syndrome with ocular and brain malformations [81, 82]. In its severe form, nephrotic syndrome manifests from birth with anuria, and is histopathologically characterized by DMS with irregular lamellation of the glomerular basement membrane [81, 83, 84]. Owing to reduced fetal urine output, pulmonary hypoplasia with hypertension and respiratory distress at birth may occur [84]. Congenital nephrotic syndrome may occur with or without ocular abnormalities [83]. Milder presentations include childhood-onset macroscopic hematuria with albuminuria and varied neurodevelopmental and ocular findings [83, 85–87]. Histopathological findings included FSGS with segmental podocyte foot process effacement and thin basement membrane on electron microscopy [87]. Ocular abnormalities, such as microcoria (narrow, nonreactive pupils), were among the original reports of Pierson syndrome. Other features include glaucoma and abnormalities of corneal diameter, iris, and lens [88], retinal thinning, pigmentary changes, detachments and secondary optic atrophy [89]. More recently, the Waters' group described optic nerve hypoplasia as a phenotypic variant of Pierson syndrome [87]. Severe hypotonia at birth has been reported as a feature of Pierson syndrome [84]. Survival owing to initiation of renal replacement therapy early has led to descriptions of psychomotor retardation, severe muscular hypotonia, and blindness in children who survived until the age of 1.3–4.8 years [90]. Alterations in skeletal muscle tissue from one case were compatible with a chronic denervating process [90]. Brain malformations described in later childhood presentations included agenesis of corpus callosum and anterior pituitary hypoplasia, and was associated with seizures, nystagmus, learning difficulties, and growth hormone deficiency [87].

SRNS and Central Nervous System Abnormalities

Galloway-Mowat Syndrome

Galloway-Mowat syndrome (OMIM 251300) is a rare AR-disease consisting of microcephaly associated with SRNS and in some cases with hiatus hernia [91]. GAMOS is clinically and genetically heterogeneous and should be considered in children even in the absence of renal involvement at presentation [92]. Renal abnormalities range from isolated proteinuria to SRNS, the latter, typically presenting in the first months of life and most often rapidly progressing to kidney failure within a few months. Premature death in childhood is common, most often from complications from renal failure. However, there are rarer cases with preserved kidney function in adulthood [93]. Kidney biopsies have revealed various histopathology including DMS, MCD/FSGS, mesangial proliferation, and increased mesangial matrix [93, 94]. Central nervous system abnormalities can either manifest at birth as a reduced head circumference for gestational age (primary microcephaly), irritability, and roving eye movements. If not present at birth, microcephaly can become evident over time (secondary microcephaly) [92]. Clinically, affected patients may present with developmental delay, psychomotor delay, various degrees of intellectual disability, hypotonia, extrapyramidal movements, visual impairment with optic atrophy, and propensity to seizures [95]. Imaging and histologic findings include abnormal cerebral gyri or cerebellar atrophy, lack of cortical stratification, immature cortical neurons, improper orientation of cortical neurons, and glioneuronal ectopias in the leptomeninges, hypomyelination involving the brain stem, spinal cord, and cerebral hemispheres; and complete absence of the internal granular layer of the cerebellum. The dentate gyrus within the hippocampal formation may be absent and the inferior olivary nuclei hypoplastic [96]. Coarsened facies, full lips and cheek, bushy eyebrows, wide nasal root, sloping forehead, pinched nose, micrognathia, and large ears have been described [97]. Disease-causing variants have been identified in ten genes to date: *OSGEP, TP53RK, TPRKB, LAGE3,* and *GON7* encoding the five subunits of the KEOPS complex [98, 99], and *YRDC involved in the same pathway* [99*],* along with *WDR4* [100], *WDR73* [92], and *NUP107* and *NUP133* [96, 100]. *WDR73*, *WDR4*, *NUP107*, *NUP133,* and *GON7* biallelic variants are responsible for more attenuated neurological and renal phenotypes than those associated with variants in *YRDC* gene or in the four other KEOPS genes [92, 98–100].

Less Common Early-Onset SRNS with Intellectual Disability

ARHGDIA Nephropathy

Biallelic *ARHGDIA* missense loss-of-function variants cause infantile onset SRNS with DMS [101]. Intellectual disability was reported in three children, one with sensorineural hearing loss and another with seizures and cortical blindness.

KANK4 Nephropathy

Intellectual disability, facial dysmorphism, and atrial septal defects are extra-renal features of biallelic variants in kidney ankyrin repeat-containing protein 4 (*KANK4*) associated SRNS [102]. KANK2 interacts with ARHGDIA, another infantile SRNS gene regulating the podocyte cytoskeleton [102]. In addition, Gee et al. also discovered rare variants in the related genes *KANK1* and *KANK2* in families with SSNS.

Mitochondropathies that also often present with intellectual disability are discussed in chapter "Mitochondropathies."

SRNS and Peripheral Neuropathy

Charcot-Marie-Tooth Disease

Charcot–Marie–Tooth disease refers to a heterogeneous group of inherited chronic peripheral motor and sensory neuropathies [103]. Boyes et al. reported that *INF2* variants are a major cause of Charcot–Marie–Tooth disease associated with FSGS (OMIM#614455), accounting for approximately 75% of all cases [50]. Progressive distal muscle atrophy with walking difficulties, limited hand function, muscle wasting, and abolition of deep tendon reflexes in the lower and upper limbs with foot and hand deformities are the typical manifestations of the disease. Twelve index patients with *INF2* monoallelic variant presented with proteinuria at a median age of 18 [10–21] years, and kidney failure developed in 11 at a median age of 21 [12–47] years. All patients exhibited lesions of FSGS, but full-blown nephrotic syndrome was noted in only 5 [50]. Median age at onset of peripheral nerve dysfunction was reported to be 13 years (range 5–28). Conduction velocities of the median nerve were intermediate (23–45 m/s). Mild or moderate sensorineural hearing loss was reported in 4 of the 12 families (33%) with an *INF2* monoallelic variant, which is higher than the approximately 5% prevalence reported among patients with Charcot–Marie–Tooth disease [50]. Sural-nerve biopsy specimens display a combination of axonal and demyelinating changes, characterized by marked decrease in myelinated fibers, as compared to age-matched controls, and numerous multilayered "onion bulbs" [50].

SRNS and Skeletal Dysplasia

Schimke Immuno-Osseous Dysplasia

Schimke immuno-osseous dysplasia (OMIM#242900) [104] is a rare AR-multisystemic disorder characterized by spondyloepiphyseal dysplasia, progressive kidney failure associated with FSGS, variable lymphopenia defective cellular immunity, and arteriosclerosis caused by biallelic variants in *SMARCAL1* [105]. Children typically present in early childhood with SRNS and FSGS [106]. Remarkable extra-renal features include growth retardation with radiological evidence of spondyloepiphyseal dysplasia (Fig. 1). Examination of the skin reveals lentigines on the torso. Hypothyroidism, Moya-Moya disease, and transient ischemic attacks are other features. Facial features have been reported to include a triangular shape, a broad nasal bridge, and a bulbous nasal tip. Early death is common and mainly related to opportunistic infections or cardiovascular events [106]. Specific therapy includes infection prophylaxis, hematopoietic growth factors for neutropenia, orthopedic surgery as required, and combined kidney and bone-marrow transplantation [107, 108].

Nail Patella Syndrome

Nail patella syndrome or hereditary onycho-osteodysplasia (OMIM#161200) [109] is a rare AD-disease that affects multiple organs including the limbs, skeleton, kidneys, and eyes. Dysplasia of the nails and absent or hypoplastic patellae are the cardinal features; other features include dysplasia of the elbows, presence of iliac horns, and nephropathy. Renal manifestations occur in 30–50% of patients and typically include proteinuria with or without hematuria and nephrotic syndrome (5–10% cases), which progresses to kidney failure over varying periods of time. Histological

features include FSGS or renal dysplasia. Electron microscopy shows thickened basement membranes. Additional features include open angle glaucoma and ocular hypertension, which usually develop during adulthood and occur in ~10 and 7% of patients, respectively. Nail patella syndrome is caused by monoallelic loss-of-function mutations in the *LMX1B* gene [110]. Specific *LMX1B* variants cause AD-FSGS but no ultrastructural glomerular basement membrane anomaly suggestive of nail patella-like renal disease, and no extra-renal features [111].

SRNS and Skin Disorders

ILNEB Syndrome

ILNEB syndrome (OMIM#614748) is characterized by interstitial lung disease, congenital or infantile-onset nephrotic syndrome, epidermolysis bullosa, and sparse hair with nail defects [112] (Fig. 2). Kidney biopsies reveal FSGS with trilamellation of the glomerular basement membrane on electron microscopy. Respiratory distress, manifesting from birth with severe reticulonodular changes on chest X-ray has been reported. From early infancy, increasing skin fragility with small blisters and erosions are described. Sparse hair, eyebrows, and eyelashes are observed in association with dystrophic nails and distal onycholysis.

SRNS and Storage Disorders

Disorders of Sphingolipid Disorders

SGPL1 biallelic loss-of-function variants cause sphingosine-1-phosphate lyase insufficiency syndrome (SPLIS, OMIM#617575) characterized by SRNS and primary adrenal insufficiency, immunodeficiency, and neurological defects [113, 114]. Its phenotypic expression is variable, from severe multi-systemic forms, associated with fetal hydrops and early mortality, to isolated single organ disease.

Nephropathy is associated with other genetic disorders of sphingolipid metabolism, such as Fabry and Gaucher disease, and sphingolipid accumulation is reported in glomerular disease of non-genetic origin [115].

Lysosomal Storage Disorder

Sialidosis (OMIM#256550) [27] is a rare AR-lysosomal storage disease due to biallelic loss-of-function variants in *NEU1* encoding for neuraminidase [116]. Disease manifestations can be considered as a milder type I phenotype, characterized by macular "cherry red" spot where myoclonus manifests in adulthood, or the more severe type II that has congenital or infantile onset. Individuals affected by sialidosis type II exhibit typical storage disease features, such as coarse face with low set ears, hepatomegaly, bilateral hearing loss, developmental delay, hip

dysplasia, and brachycephaly. Bilateral mild frontotemporal atrophy is observed on cranial MRI. Presentation can include antenatal hydrops, infantile onset nephrotic syndrome, childhood isolated proteinuria [117]. Although rare, nephrosialidosis should be considered in children with SRNS if kidney biopsies exhibit severe vacuolar degeneration of renal epithelial cells [118].

Action myoclonus-renal failure syndrome (OMIM#254900) is an AR disease characterized by progressive myoclonic epilepsy associated with renal failure. It is caused by biallelic pathogenic variants in *SCARB2* encoding lysosomal integral membrane protein-2 [119], the receptor for β-glucocerebrosidase, a lysosomal enzyme deficient in Gaucher disease [120]. It typically presents at 15–25 years of age with proteinuria, FSGS and neurological symptoms including tremor, action myoclonus, seizures, and later ataxia, while cognitive function is preserved [121]. Kidney failure usually occurs within 5 years after onset of proteinuria [121].

Reverse Phenotyping and SRNS Phenocopies

With availability of NGS, a number of kidney diseases have now been recognized as phenocopies of SRNS. A phenocopy is a phenotypic trait or disease that resembles the trait expressed by a particular genotype, but in an individual who is not a carrier of that genotype [122]. An example is the report that 10% of patients with FSGS may have molecular diagnosis consistent with Alport syndrome due to *COL4A3, COL4A4, or COL4A5* defects [123]. Similarly, a prevalence of 4% of *PAX2* (papillorenal syndrome gene) monoallelic variants was reported in a cohort of familial non-syndromic FSGS [124]. Another example of phenocopy is the biallelic p.Pro209Leu variant in the ciliary gene *TTC21B*, previously known as a cause of nephronophthisis, and now identified in adolescents with albuminuria, hypertension, and conjunction of tubular basement membrane thickening and FSGS on kidney biopsy [125]. Biallelic *CUBN* variants are a novel cause of podocytopathy with non-nephrotic albuminuria [126]. Variants in *CUBN* encoding cubilin, an intestinal and proximal tubular protein uptake receptor, were previously known to cause the Imerslund-Grasbeck syndrome (OMIM#261100) associating megaloblastic anemia with malabsorption of vitamin B12, and mixed proteinuria. Simons' group identified *CUBN* biallelic pathogenic variants in 39 patients with chronic benign proteinuria up to 1.5 g/day with >50% albumin, and no or minor kidney lesions and normal kidney function [127]. *CUBN*-related proteinuria was often mistaken by clinicians for early-stage SRNS and patients received RAASi that were ineffective. Albuminuria due to cubilin defect is therefore considered a benign condition, and may not require any proteinuria-lowering therapy or kidney biopsy.

Warejko et al. carried out large-scale whole exome sequencing in a cohort of patients with SRNS and reported that up to 5% may have phenocopies of SRNS [128]. Pathogenic variants in *COL4A3-5, AGXT, CLCN5, CTNS, FN1, GLA, and WDR19* genes were identified as phenocopies of podocytopathies in this study. To define better true phenocopies of SRNS, the Romagnani group examined the whole exome of 64 patients with SRNS for pathogenic variants in 298 chronic kidney disease genes, and reassessed the clinical features of the patients (reverse phenotyping). In this cohort, 30% of patients had mutations in podocytopathy genes while 28% had mutations in phenocopy genes identified previously, and also in *FAT1* and *FAT4* [129]. In the 28% patients with mutation in phenocopy genes, clinical reassessment of patients and their families led to identification of subtle features of the genetic diseases suggested by the sequencing data [129]. This study showed clearly that whole exome sequencing combined with reverse phenotyping doubles the diagnostic yield from genetic testing and results in accurate diagnosis and appropriate therapies.

Complex Inheritance

In addition to the Mendelian forms described above, there may also be a complex transmission of SRNS, which may lead to the absence of molecular diagnosis. This is the case, for instance, of susceptibility variants, or rare cases of digenism described as the cause of SRNS. Several genetic susceptibility factors to SRNS/FSGS have been identified in recent years through genome wide association studies (GWAS) or other high-throughput techniques. The most important advance has been the discovery of variants of the *APOL1* gene encoding the apolipoprotein L1 in African-Americans with various nephropathies [130]. The at-risk G1 and G2 alleles are enriched in the biallelic state in West-African and West Indian populations because they confer the resistance to trypanosomiasis [130]. However, the presence of both alleles significantly increases the risk of SRNS in adults and children [130–135]. SRNS associated with two *APOL1* risk-alleles is associated with faster progression to kidney failure, but similar sensitivity to steroids, cyclosporin, or mycophenolate mofetil/dexamethasone compared with other subjects [131, 133]. It is usually not associated with other causative variants in monogenic SRNS genes [134].

Moreover, “additional” heterozygous variants in a gene involved in the development of SRNS have also been found in a few individuals, sometimes associated with a more severe phenotype, suggesting the existence of genetic epistasis [9, 136, 137]. Epistasis describes how gene interactions can affect phenotypes. Examples of digenism and gene modifiers have been reported [9, 136, 138]. Digenism refers to the concept that variants in two distinct genes may interact genetically to manifest a phenotype. For instance, Ars group reported two pedigrees of SRNS/FSGS related to *NPHS2* or *INF2* variants, in which patients carrying an additional *COL4A3* variant had a more severe phenotype [9]. Larger studies are necessary to confirm the role of genetic epistasis in the development of SRNS.

Phenotypic variability is also characterized by the rare occurrence of gene variants in children with nephrotic syndrome that is steroid-sensitive at least at diagnosis and also in children with SRNS (see below) [102, 139]. In such complex cases, it is crucial to ascertain the complete response to steroids or other immunosuppressive drugs [7]. Indeed, RAASi and/or calcineurin inhibitors (CNIs) may enable partial or even nearly-complete remission of proteinuria, even in case of monogenic SRNS. Moreover, the pathogenicity of the identified variants should be confirmed through functional studies, and considering their allelic frequency in different populations.

Familial Forms of Steroid Sensitive Nephrotic Syndrome

SSNS is overwhelmingly due to interaction between different variants in many genes including multiple immune response modulator genes and environmental factors such as lifestyle, diet, exposure to certain pathogens, and other factors [140, 141]. A strong evidence for this is the identification of multiple loci in the HLA region in different populations [142–146]. In addition, anecdotal monogenic causes of SSNS have been reported in the literature despite the fact that 80–90% of all childhood nephrotic syndrome have SSNS response pattern, in contrast, over 60 genes have been identified as single gene causes of SRNS despite the fact that only 10–20% of all NS patients have this pattern of therapy response [140, 141]. It has been estimated that 3% of children with SSNS may have an affected sibling or first degree relative, and there have been published case reports of familial SSNS [139, 147–151]. Similar rates of recurrence in siblings are found for majority of multifactorial (complex) human traits. Dorval et al. reported on the clinical data in families with SSNS comprising of 33 families with possible autosomal recessive mode of inheritance and 29 with autosomal dominant disease [152]. Exome sequencing in this cohort did not identify any monogenic cause of SSNS, however, variants in *HLA-DQA1* were found to be highly linked to the disease in this cohort suggesting that most SSNS are due to complex inheritance and variation in immune response genes are overwhelmingly important in etiology and pathogenesis of SSNS [152]. Few monogenic causes of SSNS have been reported in the literature, including *EMP2*, *KANK1* and 2, *MAGI2* variants [36, 102, 139, 153–156]. Most of these genes shared the features of not causing SSNS exclusively as some individuals in the same family carrying the same variant and other families have variable response patterns ranging from SRNS to frequent relapsing/steroid-dependent course [36, 102, 139, 153–156]. Apart from *FOXP3* that is also associated with T-cell regulation defects [153], products of most of the other genes are not linked to the immune system, but they are important for the structure and function of the podocyte [36, 102, 139, 154–156]. The mechanisms by which defects in podocyte genes will cause steroid-responsive disease is currently under investigation.

Phenotyping

The work-up recommended at diagnosis to search for extrarenal manifestations, suggesting a syndromic form of SRNS is listed in Table 2 [7]. Particular attention should be paid to neurological, eye, ear, genital, and skeletal examinations. Parents and siblings should be offered urinalysis and genetic counseling.

Principles of Treatment

Despite limited experience with treatment of genetic SRNS, clinical practice recommendations of the International Pediatric Nephrology Association for management of children with SRNS including genetic forms have been published in 2020 [7].

Supportive Therapy

Measures to prevent consequences of active disease are detailed in ▶ Chap. 14, "Steroid-Sensitive Nephrotic Syndrome." These include RAASi to reduce proteinuria, cautious use of diuretics, prompt detection and treatment of hypertension, vaccinations, supplements of vitamin D and thyroid hormone if required, and management of chronic kidney disease. Extra-renal features should be managed by multidisciplinary teams.

Table 2 Initial phenotypic work-up of a child with genetic SRNS

Clinical evaluation
Family history • Renal and extrarenal manifestations • Consanguinity
Patient history • Pregnancy and neonatal data • Dipstick at home; urinary protein/creatinine, blood albumin; complete/partial response to therapy • Kidney biopsy results • Genetic results
Physical exam (interdisciplinary evaluation, depending on underlying disease and extrarenal features) • Growth charts: Height/length, weight, head circumference • Dysmorphic features • Ambiguous genitalia • Neurological examination; assessment of cognitive status • Orthopedics: Absent or hypoplastic patella, spondyloepiphyseal dysplasia • Eyes: Microcoria, cataract, glaucoma, optic atrophy, keratoconus, macular spots, lenticonus, nystagmus • Dermatology: Epidermolysis bullosa, icthyosis
Imaging
• Renal ultrasound: Renal echogenicity and size of kidneys • Brain MRI: In case of microcephaly, psychomotor delay, neurological signs • Cardiac ultrasound: In case of *NPHS2*, *CRB2*, *COQ2* biallelic variants • Audiology: Suspicion/risk of sensorineural hearing loss
Specific lab tests
• Lymphocyte immunophenotyping: T cell immunodeficiency (in case of *SMARCAL1* biallelic variants)

Immunomodulators

It has been established in multiple studies that >95% of all genetic SRNS are resistant to glucocorticoids and conventional second line agents (chapters "Treatment of SRNS" and "NS Complications.") Currently, the approach of most pediatric nephrologists is to offer supportive therapy and measures to slow progression of chronic kidney disease. Preclinical studies suggest that glucocorticoids and other immunosuppressive agents may have non-immunomodulatory stabilizing effects on podocyte actin cytoskeleton and the slit diaphragm [157–159]. Xing et al. showed that dexamethasone upregulates the expression of nephrin and tubulin-α in cultured human and murine podocytes [159]. Another study showed that the anti-proteinuric effects of calcineurin inhibitors (CNI) might be mediated by intra-renal hemodynamic changes, inhibition of calcineurin-mediated degradation of synaptopodin, and stabilization of the podocyte actin cytoskeleton [157]. Notwithstanding these effects, most case series emphasize that the overwhelming majority of children with genetic SRNS will not achieve complete remission to corticosteroid or CNI-based therapy, while very few will achieve partial remission [14, 36, 139, 160, 161]. Considering the benefits of partial remission and the impact of delaying progression to kidney failure even for few years on the quality of life of children with SRNS, there may be a place for limited trials of these agents. In a recent review, Gbadegesin et al. proposed a pragmatic approach of discussing the uncertainty of benefits of therapy with parents, coupled with a low threshold for discontinuing therapy if the patient is unresponsive [162]. There is a need for randomized clinical trials to evaluate the usefulness of existing agents, repurpose drugs, and develop novel therapies for the treatment of genetic forms of SRNS.

Targeted Therapy

One of the promises of the advances in genomic science and technology is that identification of genetic causes for SRNS will lead to better understanding of disease mechanisms and identification of targeted therapeutic agents. Despite the fact that we now know >60 monogenic causes of SRNS, only few novel therapeutic targets have been identified. The reasons for this are subjects of recent reviews [162, 163]. Some of the genomic discoveries have led to identification of some potential targeted therapies as outlined below.

Defects in genes that are critical for COQ10 biosynthesis pathway and COQ10 supplementation: Products of multiple genes such as *COQ2*, *COQ6*, *COQ8B* (*ADCK4)*, and *PDSS2* regulate coenzyme Q10 biosynthesis. Variants in these genes have been reported as causes of syndromic and non-syndromic SRNS (see chapter “Mitochondriopathies”) [54, 164, 165]. Supplementation with COQ10, a common food supplement, may therefore represent a specific therapy for patients with CoQ10-related SRNS. Indeed, few cases of partial remission following COQ10 supplementation were reported in these patients [54, 164, 165].

CUBN variants and vitamin B12 supplements: As detailed above, albuminuria due to cubilin defect is considered benign and may not require any proteinuria-lowering agent or kidney biopsy. Whether cubilin inhibition could be a therapeutic strategy in glomerular damaging conditions needs further investigation. The variants associated with isolated proteinuria affect C-terminal residues after the cobalamin-binding domain and do not cause cobalamin deficiency, as opposed to the Imerslund-Grasbeck variants affecting N-terminal residues.

SGPL1 variants and vitamin B6 supplementation: The gene product sphingosine-1-phosphate (S1P) lyase is a vitamin B6-dependent enzyme that degrades sphingosine-1-phosphate in the final step of sphingolipid metabolism [113]. Vitamin B6 supplementation resulted in increased S1P expression and reduced sphingolipids in patients’ derived fibroblasts in some individuals with *SGPL1* variants [113]. However, the effects on disease phenotype is uncertain.

Variants in genes that modulate Rho-like GTPases (RhoA/Rac1/Cdc42) and therapy with mineralocorticoid receptor blockers: These small Rho-like GTPases are known to interact with mineralocorticoids; it is therefore plausible to speculate that mineralocorticoid-receptor blocker such as eplerenone may represent a targeted therapy for patients with SRNS due to mutations in genes that are critical for these pathways [101, 166, 167].

Principles of Transplantation

Children with genetic forms of SRNS often progress to kidney failure owing to a paucity of effective treatment strategies. Kidney transplantation should be offered, with rare exceptions. In patients with severe comorbidities and/or under circumstances with limited medical resources, the decision to proceed with a transplantation can be taken by the medical team after discussing with the families. The long-term post-transplant outcome is excellent [168] and similar to that of children transplanted for other causes [169].

In addition to the risks inherent to any kidney transplant in children, the persistent nephrotic state increases the risk of vascular graft thrombosis. Therefore, uni- or bilateral nephrectomy should be considered at the time of preparing for the kidney transplant [7]. Bilateral nephrectomy is also recommended in case of *WT1* pathogenic variant due to the risk of malignancy. The anticipated recurrence risk after transplantation should be discussed with the family (see below).

Selection of Organ Donors

Living-related kidney donation in the context of genetic SRNS must be preceded by a detailed evaluation of the donor, mode of disease transmission, and by genetic testing and counseling [7, 64]. Heterozygous carriers of autosomal recessive SRNS variants can be kidney donors. Exceptions to that are monoallelic (i.e., heterozygous) defects in collagen IV genes (i.e., *COL4A3*, *COL4A4* and *COL4A5* in females) who should be discouraged from kidney donation because they may develop kidney failure [7, 170]. Also, the parent may rarely bear another pathogenic variant on the second allele, such as the frequent p.Arg229Gln *NPHS2* variant and therefore be at risk of developing SRNS later in life [32, 33]. In cases of autosomal dominant SRNS, living-related kidney donation is also discouraged. Moreover, incomplete penetrance is observed in families with AD-pathogenic variant such as *WT1* variant.

Recurrence of Genetic Forms of SRNS

Recurrence of proteinuria occurs in 30–50% of children with SRNS/FSGS and is the leading cause of pediatric allograft loss, but in only 3–8% in case of identified monogenic disease [13, 15, 171–173]. Indeed, most children with genetic SRNS do not recur after transplantation due to correction of the underlying genetic defect [173]. Post-transplant recurrence of proteinuria has been reported in some patients with variants in *NPHS1*, *NPHS2*, *ACTN4,* and *WT1* genes [174, 175]. *NPHS1* variants are the most-common and unraveled cause of post-transplant proteinuria recurrence [174]. Twenty-five percent of children with *NPHS1* Fin-major/Fin-major variants (that result in the absence of nephrin in the native kidney) experience recurrence of proteinuria at a mean time of 12-months post-transplantation (range 5 days-48 months) [176, 177]. Anti-nephrin auto-antibodies have been identified in recurrent disease in half of cases reported [174, 176]. Therefore, the disease is rather a de novo nephrin antibody-mediated disease than a recurrent SRNS due to *NPHS1* defect. Recurrence of proteinuria has been reported in some patients with *NPHS2* missense variants, as well as in three children with either a missense (p.Trp59Arg) *ACTN4* variant, a splice-site (IVS9+4C>T) *WT1* variant, and *NUP93* biallelic variants [13, 175, 178, 179]. Proteinuria recurrence in patients with *NPHS2* variants have included patients where identified variants were of uncertain significance or single heterozygous variants that do not cause genetic SRNS alone [174, 176]. Bertelli et al. described recurrence in five of 13 (38%) patients with homozygous ($n = 9$) or heterozygous ($n = 4$) podocin mutations compared to 15 of 40 (44%) non-*NPHS2* FSGS patients [180]. However, among the five patients described as having *NPHS2* mutations and recurrence, three had only heterozygous variants predicted to be either benign or polymorphisms with the Polyphen software program [13]. When only patients with biallelic pathogenic *NPHS2* variants are taken into account, the risk of recurrence significantly decreases, concordant with the low recurrence rate of 3–8% reported in other studies [13]. Anti-podocin auto-antibodies have never been identified [180, 181].

In summary, the post-transplant recurrence of genetic SRNS is a very rare phenomenon. While some have a clear pathophysiology, others deserve caution and should lead to a reinterpretation of the cause of post-transplant proteinuria, and of the pathogenicity of the identified variants by an expert geneticist.

Perspectives

Hereditary forms of nephrotic syndrome are far more common than previously thought 20 years ago. The highest rates of variant detection are in patients presenting with SRNS in the first year of life and subsequently decrease among older patients [6]. Most of the cases with hereditary forms of SRNS have a disease onset within early childhood, are resistant to immunosuppressive therapy, and do not recur after kidney transplantation. As a large proportion of patients with SRNS do not have an identified underlying genetic defect, and given the complexity of the pathophysiology of the kidney, numerous further genes are expected to be mutated in SRNS. The most recently identified SRNS genes are rare and only few families are affected. Their discovery does not usually lead to further research due to the small number of families involved. It is therefore difficult to establish the pathogenicity of these variants and the real involvement of these genes in the kidney physiology, in the absence of a robust in vitro or in vivo model. Moreover, in patients with multidrug-resistant SRNS, no post-transplant recurrence, and in whom no mutation has been identified, we can hypothesize one or more deep intronic mutations, not revealed by panel or exome sequencing techniques, as recently demonstrated by comprehensive genome sequencing in a 9-year-old boy with SRNS due to *NUP93* variants: an exonic nonsense and an intronic one leading to aberrant splicing [182]. However, NGS and genome sequencing approaches face the difficulty of determining the causal variant(s) among a great number of potential pathogenic variants. It is also plausible that more complex patterns of inheritance, as described in patients bearing bi- or tri-allelic variants, or as observed with the p.Arg229Gln *NPHS2* variant [32] will be increasingly recognized. Indeed, disease predisposing variants may lead to variable phenotypic expression and penetrance depending upon unidentified environmental and genetic factors [38]. Moreover, common variants in genes expressed in podocytes may account for an increased risk of FSGS and kidney failure observed in selected ethnic groups, as has been described with the *APOL1* gene. To date, several fascinating disorders, such as familial forms of SSNS, connecting podocyte physiology and the immune system, remain incompletely solved.

The constant advances in the understanding of hereditary kidney diseases and renal physiology also open the way for therapeutic innovations. A promising therapy, still explored at a basic level, involves protein chaperones. These drugs redirect the trafficking of missense mutant proteins to the plasma membrane when abnormally retained in subcellular organelles. Additional encouraging results have been obtained with drugs that stabilize the podocyte actin cytoskeleton. It is now clear that genetic diagnosis of cases with SRNS is necessary to allow for accurate genetic counseling, to avoid ineffective therapies and even start early suitable treatment such as ubiquinone in COQ10 deficiency, and hopefully in the near future, to offer specific mutation-based therapies.

Abstract

The glomerular basement membrane (GBM) is a vital component of the filtration barrier of the kidney and is primarily composed of a highly structured matrix of type IV collagen along with laminin isoforms, nidogens, and the heparan sulfate proteoglycans: perlecan, agrin, and type XVIII collagen. Specific isoforms of type IV collagen, the α3(IV), α4(IV), and α5(IV) isoforms, assemble into trimers that are required for normal GBM function. Mutations in these type IV collagen isoforms cause dysfunction of the GBM that varies depending on genotype and sex and is called Alport syndrome. Classic Alport syndrome is characterized by glomerular hematuria with variably progressive chronic kidney disease, sensorineural hearing loss, and ocular findings. Mutations in laminin β2 cause Pierson syndrome manifesting as congenital nephrotic syndrome. Additional disorders with abnormal findings in the GBM on kidney biopsy include nail-patella syndrome and *MYH9*-related disorders.

Glomerular basement membrane · Alport syndrome · Pierson syndrome · Type IV collagen · Laminin · Extracellular matrix · Renin-angiotensin-aldosterone pathway

The Glomerular Basement Membrane

Basement membranes are complex extracellular scaffolds that provide support for continuous layers of cells such as the endothelial cells lining blood vessels or epithelial cells lining tubular structures. The glomerular basement membrane (GBM) is one of the most investigated basement membranes in the human body, and this can be attributed to human kidney disease phenotypes such as Alport syndrome. The earliest descriptions of basement membranes came from the work of William Bowman, an English surgeon, anatomist, and histologist who lived between 1816 and 1892 [1]. In an article published by the Royal Society in 1842, Bowman described the structure and use of the Malpighian bodies of the kidney. He described kidney tubules and wrote that “These tubes consist of an external tunic of transparent homogeneous tissue (which I have termed the basement membrane), lined by epithelium” [2]. Together with these careful descriptions, Bowman created detailed sketches based on the appearance of the nephron by early light microscopy. Since those early descriptions, knowledge of basement membrane structure and composition has advanced significantly.

All basement membranes consist of core components that include laminin isoforms, type IV collagen, nidogens, and the heparan sulfate proteoglycans: perlecan, agrin, and type XVIII collagen. From studies of protein interactions in vitro [3] and from studies in model organisms [4], there is evidence of an order to the assembly of basement membranes. This starts with laminin, which is formed from trimers of alpha, beta, and gamma chains that create a cruciform structure (Fig. 1). These trimeric units then polymerize to form networks, which connect to cell surface receptors such as integrins and dystroglycan [3]. The laminin network is a key component for outside-in signaling to cells, and there is a wide range of human pathology associated with genetic defects affecting laminin secretion and assembly. This pathology includes skin, lung, and kidney phenotypes, highlighting the importance of laminin networks in these tissues.

Following assembly of the laminin network, type IV collagen is laid down. There are three distinct collagen IV networks in humans, and these are encoded by the genes *COL4A*1-6. From these six genes, there are six alpha chains which assemble into triple helix trimers with the combinations: α1α1α2(IV), α3α4α5(IV), and α5α5α6 (IV) [5]. The triple helix has a noncollagenous (NC1) domain, a long collagenous domain (consisting of Gly-X-Y repeats), and the 7-S domain. Trimers dimerize at the NC1 domain with a unique sulfilimine bond [6]. This bond requires the enzymatic activity of peroxidasin [7], and this reaction is catalyzed by ionic bromide [8]. Heterotrimers of type IV collagen then polymerize at the 7-S domain to form a network. Type IV collagen is an essential component of all basement membranes and is thought to provide mechanical strength. In the adult GBM, the dominant network is α3α4α5(IV), and by comparison to α1α1α2(IV), this network has a greater number of cysteine residues which may lead to increased resistance to proteolysis by virtue of increased disulfide bonds [9]. The α3α4α5(IV) network is also localized to the cochlea and basement membranes in the eye, and it is the network affected in Alport syndrome.

Laminin and type IV collagen are connected by cross-linking proteins such as nidogen [10]. In addition to these proteins, proteomic studies of extracellular matrix have highlighted many more components [11]. Over 1000 proteins have been annotated in the human matrisome [12], and a repertoire of between 140 and 200 is found in different tissues [13]. It is likely that the tissue specificity for composition relates directly to the function of extracellular matrix in these tissues. In the glomerular matrix, 144 matrisome components have been identified [11, 14], although the functional roles of many of these proteins are unknown. Using gene ontology classification,

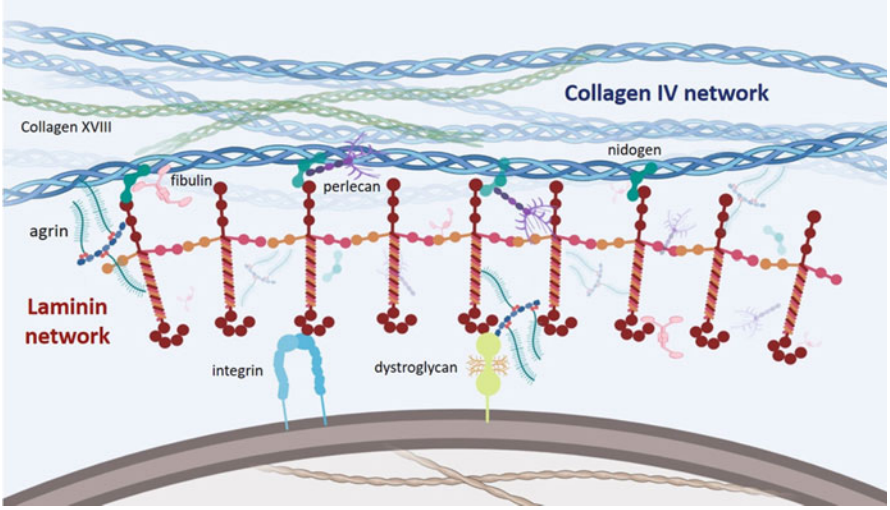

Fig. 1 Major components of basement membranes. Laminin and type IV collagen networks are core components of all basement membranes, and these networks are connected by cross-linking proteins such as nidogen and perlecan

there are approximately 40–50 basement membrane components, and many of these will localize to the GBM [11]. It is harder to know which cells are responsible for producing specific GBM components, although studies of laminin have shown contribution from both endothelial cells and podocytes [15], and for the α3α4α5 (IV) network of collagen IV, this is exclusively podocytes [16].

The GBM is a fusion of two separate endothelial- and podocyte-derived basement membranes that merge during glomerular development. As such, it is thicker than most basement membranes. The average GBM thickness for adult males is 373 nm and for adult females is 326 nm [17]. However, GBM thickness also changes with age from 194 ± 6.5 nm at 1 year to 297 ± 6.0 nm at 11 years [17, 18] in line with overall increases observed in glomerular size with age. Imaging of the GBM with light and electron microscopy is a fundamental requirement of the diagnostic evaluation of kidney biopsies, and kidney pathology is one of the few examples where tissue ultrastructure is a routine component of biopsy evaluation. Indeed, the use of electron microscopy since its origins in the 1950s has made a huge impact on our understanding of the structural features of the glomerular filtration barrier. In studies of the glomerulus using electron microscopy, Karnowsky described a “highly ordered, isoporous substructure of the glomerular slit diaphragm… with alternating, periodic cross bridges extending from the podocyte plasma membranes to a central filament which ran parallel to and equidistant from the cell membranes” [19]. These structural studies were a fundamental basis for building understanding about glomerular function.

Function of the Glomerular Basement Membrane

The glomerular filtration barrier is a specialized capillary wall. It is formed by specialized, fenestrated endothelial cells that line the glomerular capillaries, the podocytes which form a layer of interdigitating cells on the outer surface of the capillaries, and the intervening GBM (Fig. 2). In adults, approximately 180 L of blood per day is filtered by glomeruli, creating an ultrafiltrate which then passes into the tubules of the nephron. The majority of the filtrate is reabsorbed by tubular cells, and the remaining 1–2 L is excreted as urine. Although this process has been appreciated for decades, the mechanism of size-selective filtration is still not fully understood. Furthermore, the contribution of the GBM to filtration is also unclear, reflecting the difficulty in experimentally resolving size selectivity as a function of the glomerulus. The complex and intricate arrangement of podocyte foot processes meant early models of filter size selectivity described in the podocyte slit diaphragm as the major determinant. This concept was supported by measurements that showed the average spacing between podocyte foot processes is comparable to the size of albumin [19, 20]. However, more recent discoveries have questioned this concept, and these more recent studies are described below.

The glomerular albumin sieving coefficient, which is the ratio of the filtrate albumin concentration compared to the plasma albumin concentration, was originally measured as 0.00062 in rats, using fractional micropuncture [21]. This suggests that only a small amount of albumin (22.9 μg/ml filtrate) crosses the filtration barrier and enters the proximal tubule. However, an alternative method of measuring albumin filtration by tracking fluorescently labelled albumin using two-photon microscopy calculated the sieving coefficient as 0.0341, which is 50 times higher [22]. This would demand much greater reabsorption of filtered albumin through the megalin-cubulin endocytic pathway [23] to achieve normal levels of albumin excretion. However, such high levels of albumin reuptake are questioned, and therefore, the true sieving coefficient for albumin in the glomerulus remains controversial.

The endothelial glycocalyx may also contribute to size-selective filtration in the glomerulus. Glycocalyx is a gel-like layer of proteins and glycosaminoglycan (GAG) chains (heparan sulfate, chondroitin sulfate, and hyaluronan), and within the endothelium, it is positioned in the

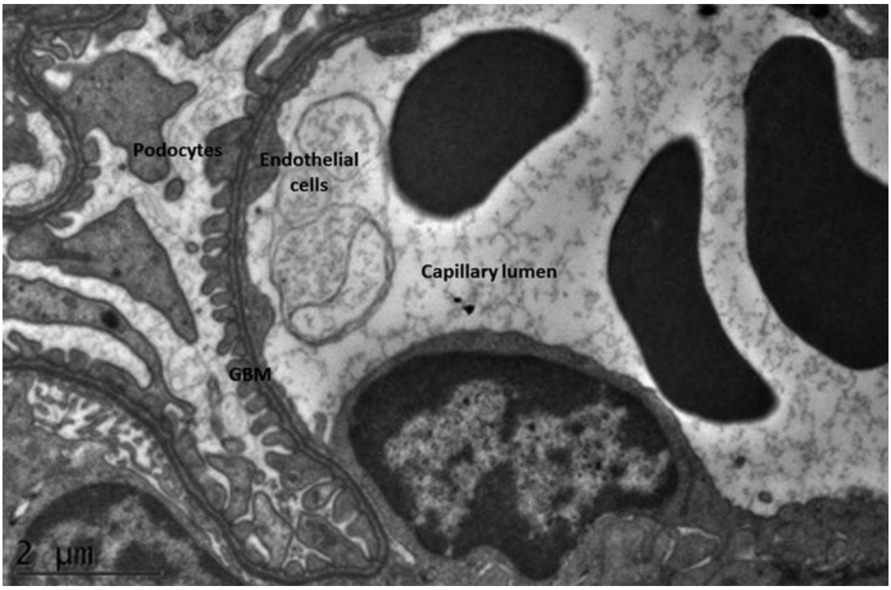

Fig. 2 The glomerular capillary wall is composed of endothelial cells, podocytes, and an intervening glomerular basement membrane (GBM). Red blood cells are visible in the capillary lumen. (Transmission electron microscopy of mouse glomerulus courtesy of Rachel Lennon)

fenestrae and anchors down to the underlying GBM [24]. Enzymatic breakdown of the GAGs that make up the endothelial glycocalyx [25] or displacement of the glycocalyx by hypertonic sodium chloride [26] caused up to a 12-fold increase in albumin filtration. However, the role of the endothelial glycocalyx was questioned by recent in vivo experiments in which the GBM was implicated as the major sieve component of the glomerular filter. Oliver Smithies proposed that the GBM is a gel [27] and should fit with Ogston's 1958 gel permeation principle [28]. If true, the GBM would determine the permeation of macromolecules through the filter in a size-dependent manner through diffusion, whereas water and ions pass through the filter by flow generated from hydraulic pressure [27]. In this model, the fenestrated endothelium and the podocyte slit diaphragms do not act by size selection, but rather provide resistance to the capillary fluid flow. The gel permeation/diffusion model was ultimately supported by a study that used variably sized gold nanoparticles [29]. Large nanoparticles (equivalent in size to IgG dimers) permeated into the subendothelial GBM, but never entered its central region. Smaller nanoparticles (equivalent in size to IgG monomers) were able to partially permeate into the central region. Nanoparticles equivalent in size to albumin (which is much smaller than IgG monomers) were able to permeate across the GBM. When albumin nanoparticles were injected at low concentration, the proximal tubular cells were able to reabsorb these particles, but the injection of high concentrations saturated the reabsorption capacity of the proximal tubules resulting in albuminuria. Intriguingly, the gold nanoparticles used in these experiments frequently aggregated upstream of slit diaphragms at the approximate position of the podocyte glycocalyx. Nanoparticles did not accumulate at the endothelial glycocalyx or at the protein bridges that form the slit diaphragm. These findings led to the conclusion that the GBM (acting as a relatively dense gel) and the podocyte glycocalyx are the two major sites that determine size selectivity in the glomerulus [29]. An explanation for why the podocyte glycocalyx acts as a barrier but the endothelial glycocalyx does not is not clear, and so, further experimental insight is required.

The gel permeation/diffusion model of glomerular filtration appears to stand up to challenge; however, absence of podocyte nephrin precludes slit diaphragm formation and causes massive proteinuria [30, 31], but this does not have a known effect on GBM composition. Rather than suggesting this as evidence for an essential role of the slit diaphragm in size selectivity, this finding may imply a requirement for the slit diaphragm in compression of the GBM to maintain its physiological thickness. Indeed, a gel compression model was recently suggested [32] and proposes that foot process effacement limits GBM compression leading to a subtle, but significant, shift from radial compression to circumferential tension. This leads to a less compressed GBM that has a larger pore size, resulting in passage of larger macromolecules. Genetic models of kidney disease, such as *Lamb2*$^{-/-}$ or *Col4a3*$^{-/-}$ mice, show podocyte foot process effacement and GBM thickening, which is consistent with a requirement for interdigitating podocyte foot processes to maintain compression of the GBM.

The GBM and cellular glycocalyx maintain a net negative charge across the filtration barrier by virtue of heparan sulfate proteoglycans with their glycosaminoglycan (GAG) side chains, which provide the negative charge. This net anionic charge led many to suggest that negatively charged molecules (such as albumin) would be repelled and selectively retained. This theory has been contested by several studies that have depleted HSPGs in the glomerulus but show no defect in glomerular function. In mice depleted of both agrin and perlecan, the net negative charge of the filter was reduced, but proteinuria was not evident [33]. Similarly, removal of heparan sulfate side chains using heparanase infusions did not lead to proteinuria [34]. In zebra fish, mutation of the *ext2* gene, which encodes exostosin glycosyltransferase 2 that polymerizes GAG side chains attached to HSPGs, led to fewer anionic sites in the GBM but did not lead to proteinuria [35]. Taken together, these results suggest that the role of charge selectivity in the glomerular filter is likely to be minor. Despite these convincing findings, anionic molecule tracers have more difficulty in passing the glomerular filter than neutral or cationic tracers [36], and as such, there is likely more to understand about charge selectivity in the glomerulus.

Basement Membrane Pathology

As essential tissue scaffolds, basement membranes are associated with pathology in many organs and tissues. In the skin, blistering disorders such as epidermolysis bullosa are caused by genetic variants in basement membrane genes such as *LAMB3* [37]. In the central nervous system, genetic defects in *COL4A1* and *COL4A2* cause hemorrhagic stroke due to weakened cerebral blood vessels [38]. In the kidney, abnormalities in the GBM accompany a wide spectrum of both genetic and acquired glomerular diseases, and these defects form the basis for disease classifications [39]. However, the mechanisms that lead to abnormal GBM morphology in glomerular disease remain uncertain, and this limits current options for therapy directed at GBM repair [40].

One of the most well-characterized GBM abnormalities is seen with Alport syndrome. This is due to impaired secretion and assembly of the key collagen IV network in the GBM. The initial appearance of the GBM in Alport syndrome is a thin basement membrane [41], and this is also seen in individuals with a single abnormal copy of the Alport genes *COL4A3*, *COL4A4*, or *COL4A5* [41]. The functional consequence of a thin GBM is microscopic and occasionally macroscopic hematuria. How red blood cells traverse glomerular capillary walls remains unclear, although it is likely that this occurs where there are significant splits or defects in the wall [42]. The reduction or absence of the α3α4α5(IV) network of collagen IV in the GBM is thought to limit the resistance of the capillary wall to the mechanical load associated with glomerular filtration. The capillary hydrostatic pressure needs to be opposed by capillary wall resistance, and if the tensile strength of the wall is deficient, this may be sufficient to create splits in the GBM. The consequence of a split GBM is a change in its morphology and composition [43], which further drives the disease progression. The characteristic basket-weave appearance of the GBM is a hallmark feature of Alport syndrome, and this abnormal GBM is associated with podocyte effacement, proteinuria, and a progressive decline in kidney function [43].

Type IV collagen is also the target of the rare autoimmune disorder, Goodpasture syndrome, where autoantibodies are directed toward the α3 (IV) chain. Unlike Alport syndrome, Goodpasture syndrome is a rapidly progressive glomerulonephritis associated with a destructive immune cell infiltration into the glomerulus [44]. Circulating anti-GBM antibodies to the α3(IV) chain serve as a useful diagnostic biomarker, and they deposit within the GBM. Therapy in Goodpasture syndrome is directed at reducing the load and production of autoantibodies with immunosuppression and antibody removal. There is currently no clear genetic basis for Goodpasture syndrome, based on abnormal type IV collagen, although interestingly familial cases have been reported [45].

The laminin network in the GBM is also affected by genetic disorders. The most well described involves variants in *LAMB2* which causes Pierson syndrome [46]. Here, the kidney phenotype is nephrotic syndrome occurring early in life and associated with ocular and neurodevelopmental defects. The GBM is thickened and there is associated podocyte effacement. The laminin 521 network is critical for signaling from the GBM to the podocyte, and these signals transmit via cell surface integrins. Integrin α3β1 is a laminin receptor and a key component of a signaling axis required to maintain intact glomerular function. Indeed, absence of either the β1 or the α3 integrin subunit results in early-onset kidney failure in mice [47]. Integrin β1 has widespread localization and function, and the total knockout is embryonic lethality. However, a podocyte-specific deletion of *Itgb1* in mice, highlights the functional importance of this integrin subunit, with early-onset nephrotic syndrome and thickened, abnormal GBM [48]. To date, no genetic defects in *ITGB1* have been linked to glomerular disease, and this likely reflects its crucial requirement for kidney development. The integrin α3 subunit has more restricted tissue expression, and the total *Itga3* knockout caused a severe lung and kidney phenotype in mice [47] with defects in the GBM. These phenotypes have also been described in patients with *ITGA3* variants associated with kidney, lung, and skin defects [49]. Overall, these examples highlight the importance of the GBM for maintaining glomerular function via a core signaling axis from the laminin network via integrin α3β1 to the podocyte actin cytoskeleton.

Common acquired glomerular disease is also associated with GBM abnormalities. Membranous nephropathy (MN), the commonest cause of nephrotic syndrome in adults, is associated with hugely expanded and distorted GBMs with immune deposits. MN is an autoimmune disorder with autoantibodies targeting podocytes antigens such as PLA2R [50] and THS7DA [51], and in pediatric MN, antibodies to semaphorin-3B have been described [52]. Thickened GBMs are also an early feature of diabetic kidney disease, where abnormal glycosylation and accumulation of advanced glycation end products may contribute. In a range of genetic and acquired glomerular disorders, the progression of disease is associated with increased matrix accumulation in the glomerulus resulting in focal segmental glomerulosclerosis (FSGS) or global glomerulosclerosis. This is a pattern of injury response, which is considered both primary and secondary, but the underlying mechanisms remain uncertain. Proteomic analysis of laser-captured glomeruli identified key molecular changes in different FSGS lesions [53], and these studies may help to further define the mechanisms which lead to FSGS and the ultimate decline in glomerular function across a range of glomerular pathologies.

Alport Syndrome

Familial hematuria was first described as a clinical entity in the early 1900s [54]. In 1927, Alport reported the association of nephritis with deafness in a large family with end-stage kidney disease (ESKD) particularly in males [55]. Numerous descriptions of families with hereditary nephritis were published in the 1950s and 1960s, leading ultimately to the observations that established Alport syndrome as a heritable disorder of type

IV collagen. These seminal events included the identification of unique ultrastructural alterations in Alport GBMs by electron microscopy (EM) [56–58], the observation that Alport GBM exhibited abnormal reactivity with anti-GBM sera directed against antigens associated with type IV collagen [59–61], the mapping of the major Alport locus to the X chromosome [62], the discovery of a type IV collagen gene (*COL4A5*) on the X chromosome [63], and finally the description of *COL4A5* mutations in families with X-linked Alport syndrome [64].

Genetics and Impact on the GBM

Mutations in any of the *COL4A3, COL4A4*, or *COL4A5* genes may adversely affect the formation and composition of affected basement membranes. If any of the α3(IV), α4(IV), or α5 (IV) chains are absent due to severe mutations, then the other type IV collagen isoforms are degraded, and no α3α4α5(IV) heterotrimers are deposited in basement membranes [65]. Milder mutations, generally missense mutations affecting the glycine residues involved in triple helix formation, may lead to the formation of abnormally folded trimers that either are degraded or lead to formation of an abnormal type IV collagen network.

There are three main genetic forms of Alport syndrome: X-linked (XLAS), autosomal recessive (ARAS), and autosomal dominant (ADAS). XLAS is caused by mutations in the *COL4A5* gene and is the predominant form of the disease, accounting for ~80% of affected patients. Affected males are hemizygotes carrying a single pathogenic *COL4A5* variant. Affected females carry a normal *COL4A5* allele as well as a mutant allele and are therefore heterozygotes. Affected females are mosaic for expression of the normal and mutant alleles due to X-inactivation [66]. Approximately 5–15% of patients with Alport syndrome have the recessive form of the disease (ARAS) due to mutations in both alleles of either *COL4A3* or *COL4A4*. These patients are either homozygotes, who have the identical mutation in both alleles of the affected gene (and who may have consanguineous parents) or compound heterozygotes who have inherited different mutations in the affected gene [67]. ADAS caused by heterozygous mutations in *COL4A3* or *COL4A4* was classically thought to be rare, affecting only about 5% of affected patients [68]. With the advent of next-generation sequencing, however, recent studies are suggesting a higher percentage of patients with AS who demonstrate autosomal dominant inheritance than was previously recognized, up to 19–31% [69, 70]. Furthermore, individuals with heterozygous *COL4A3* or *COL4A4* mutations who exhibit isolated, nonprogressive microscopic hematuria previously known as thin basement membrane nephropathy (TBMN) are now included in the category of ADAS [71]. Digenic Alport syndrome is a newly recognized genetic form of Alport syndrome with mutations in two of the *COL4A3*, *COL4A4*, or *COL4A5* genes (10, 29), and only a few patients have been reported.

Over one thousand different mutations in the *COL4A5* gene have been identified in patients and families with XLAS [72]. Mutations can be found along the entire 51 exons of the gene without identified hot spots. About 10–15% of *COL4A5* mutations occur as spontaneous events; therefore, a family history of kidney disease is not required for a diagnosis of XLAS. Reported mutations include large rearrangements (~20%), small deletions and insertions (~20%), missense mutations that alter a glycine residue in the collagenous domain of the α5(IV) chains (~30%), other missense mutations (~8%), nonsense mutations (~5%), and splice site mutations (~15%) [72–75]. The *COL4A5* genotype has a powerful effect on the phenotype of XLAS in affected males [74–76]. The position of a glycine substitution may also affect the XLAS phenotype, with 5′ glycine missense mutations causing a more severe phenotype than 3′ glycine mutations [75]. The number of side-chain carbon atoms in the substituting amino acid also influences the phenotype associated with a glycine substitution [77].

A similar variety of mutation types has been described in patients and families with ARAS [67, 73, 78–80]. There are also genotype-phenotype correlations in patients with ARAS where nonsense mutations or mutations resulting in stop codons are associated with early-onset renal failure [67]. Genotype-phenotype correlation in patients with ADAS is unknown. It is unknown why some patients with heterozygous *COL4A3* and *COL4A4* have progressive CKD whereas others have only thin GBMs and hematuria.

Clinical Features

Sex and genotype are the major determinants of the severity of kidney, cochlear, and ocular diseases in Alport syndrome (Table 1). Males with XLAS and patients of either sex with ARAS inevitably progress to ESKD, and the majority develop sensorineural deafness [67, 74]. The pacing of these events is influenced by the nature of the underlying disease mutation. While the majority of women with heterozygous *COL4A5* mutations have mild disease manifestations, ESKD and deafness develop in a significant minority [81]. Patients with ADAS exhibit relatively slow progression of kidney dysfunction, whereas hearing and ocular findings are much less common than in XLAS and ARAS [69, 82, 83].

Kidney

Persistent microscopic hematuria is the cardinal clinical feature of Alport syndrome, occurring in 100% of males with XLAS, 95% of females with XLAS, and all patients with ARAS [74, 81]. Hematuria is likely present from infancy in XLAS males and in patients with ARAS. Episodic gross hematuria is not unusual, especially during childhood [84]. Some children with Alport syndrome have virtually constant gross hematuria.

Overt proteinuria typically appears during later childhood or adolescence in boys with XLAS and in patients with ARAS. Affected children first demonstrate microalbuminuria, which progresses to overt proteinuria and even nephrotic syndrome with time [84–86]. About 75% of women with XLAS ultimately develop proteinuria of some degree [81]. Most children with Alport syndrome have normal blood pressure, but hypertension is common in adolescent males with XLAS and adolescent patients with ARAS.

In untreated males with XLAS, the probability of ESKD is 50% by age 25, 80% by age 40, and 100% by age 60 [74]. *COL4A5* genotype has a powerful effect on rate of progression to ESKD in XLAS males. Large deletions and nonsense mutations confer a 90% probability of ESKD before age 30, compared to a 70% risk with splice site mutations and a 50% risk with missense mutations [74]. A second cohort study demonstrated a median age of ESKD of 20 years for patients with truncating variants in *COL4A5* and 40 years for those with non-truncating variants (45). Risk factors for earlier ESKD also include absence of α5(IV) in the GBM and hearing loss [76]. The natural history of ESKD in ARAS is similar to males with XLAS [67]. It takes ~50 years for 50% of ADAS patients to develop ESRD, twice as long as males with XLAS [69, 82].

Women who are heterozygous for *COL4A5* mutations demonstrate widely variable disease outcomes with some women demonstrating only lifelong asymptomatic hematuria while others develop ESKD [87]. According to one study of a large cohort of women with XLAS, the risk of ESKD was 12% by age 45, 30% by age 60, and 40% by age 80 [81]. The explanation for the wide variability in outcomes for women with XLAS is unclear but likely multifactorial. Unlike in males with XLAS, genotype does not correlate with phenotype in women with XLAS, perhaps as a result of the overwhelming influence of random X chromosome inactivation on disease course in affected women [66, 81]. Risk factors for ESKD in women with XLAS include proteinuria and sensorineural deafness [81, 88]. Further studies are required to develop accurate methods to predict the risk of progressive kidney disease in women with XLAS.

Hearing

Hearing is normal at birth and during early childhood. Symmetrical deficits in sensitivity for high-frequency sounds often become detectable by audiometry in late childhood. Over time, the hearing deficit progresses into the frequency range of

Table 1 Clinical and biopsy features of Alport syndrome by genetic type

	X-linked		Autosomal recessive	Autosomal dominant
	Males	Females		
Gene	*COL4A5*	*COL4A5*	*COL4A3 or COL4A4*	*COL4A3 or COL4A4*
Clinical features (lifetime risk)				
Hematuria	100%	95%	100%	?
Proteinuria	100%	75%	100%	?
ESKD	100% (50% by age 25 years, 80% by age 40 years)	~30% by age 60 years	100%	<1% if no risk factors ~20% if risk factors are present
Sensorineural deafness	80–90% (50% by age 15 years, 75% by age 25 years)	10% by age 40 years 20% by age 60 years	>65%	Rare
Eye findings	~40%	~15%	~40%	Rare

α5(IV) in Bowman's capsule and distal tubular basement membrane	Absent in ~80%	Mosaic in ~60–70%	Present	Present

conversational speech. Because the deficit typically does not exceed 60–70 dB and speech discrimination is preserved, hearing aids are effective in most affected individuals. In males with XLAS, the probability of hearing loss is 50% by age 15, 75% by age 25, and 90% by age 40 [74]. *COL4A5* genotype influences the probability of hearing loss, with 90% of those with deletions, nonsense mutations, and splice site mutations exhibiting deafness before age 30, compared to 60% of those with missense mutations [74] (48). In women with XLAS, the probability of hearing loss is 10% by age 40 and 20% by age 60 [81]. The majority of patients with ARAS develop deafness, although precise data on timing is not available [67, 89].

Eye

Anomalies of the lens, retina, and cornea are common in Alport syndrome, especially among males with XLAS and patients with ARAS, often becoming apparent during adolescence and young adulthood [83]. About 15% of males with XLAS exhibit anterior lenticonus, in which the central portion of the lens protrudes into the anterior chamber [74]. While this lesion is often asymptomatic, it may be associated with reduced visual acuity, and cataracts and even rupture of the lens may occur. Alteration of retinal pigmentation, consisting of whitish-yellowish perimacular flecks, occurs in about 15% of males with XLAS [74, 90], often in association with lenticonus. Corneal abnormalities include recurrent corneal erosions [91, 92] and posterior polymorphous dystrophy [93]. Patients with severe *COL4A5* mutations are more likely to develop perimacular dot-and-fleck retinopathy [94]. Approximately 17% of patients with ARAS have ocular findings, whereas this is rare in patients with ADAS [89].

Others

The association of XLAS with smooth muscle tumors (leiomyomas) of the esophagus; the tracheobronchial tree; and, in women, the external genitalia has been described in several dozen families [95–97]. Symptoms such as dysphagia, postprandial vomiting, epigastric or retrosternal pain, recurrent bronchitis, dyspnea, cough, and stridor often appear in late childhood. The Alport syndrome-diffuse leiomyomatosis complex arises from a contiguous gene deletion on the X chromosome involving exon 1 of *COL4A5*, the common promoter region that regulates gene expression of *COL4A5* and *COL4A6*, and the first two exons of the adjacent *COL4A6* gene [95].

Mental retardation, midface hypoplasia, and elliptocytosis have been described in a small number of males with XLAS who carry deletions that extend downstream of the 3′ end of the *COL4A5* gene [98, 99]. Finally, abnormalities in arterial vessels have been described in males with Alport syndrome including aortic root dilatation and aneurysms of the thoracic and abdominal aorta [100].

Pathology

The clinical features of Alport syndrome originate in changes in basement membrane structure and function initiated by absence or abnormalities of α3α4α5(IV) and α5α5α6(IV) networks.

Kidney

Light microscopic abnormalities are unusual in children with Alport syndrome who are less than 5 years of age (Fig. 3A). Mesangial hypercellularity and matrix expansion, and eventually focal segmental glomerulosclerosis, are common in older children and adolescents, especially boys. Tubular atrophy and interstitial fibrosis develop progressively after age 10 in boys with Alport syndrome [101]. Prominent interstitial foam cells may be present [43] (Fig. 3B). Some patients with Alport syndrome may have FSGS lesions on kidney biopsy [102–104].

Electron microscopy may reveal pathognomonic changes, depending on the patient's age and sex. The earliest abnormality is diffuse thinning of the GBM (Fig. 3C). In some families with Alport syndrome due to *COL4A5* mutations, GBM thinning is the only ultrastructural abnormality. However, the great majority of boys with XLAS and both boys and girls with ARAS develop the classic Alport GBM lesion, consisting of diffuse thickening accompanied by "basket-weave" transformation of the lamina densa, intramembranous vesicles and densities, scalloping of the epithelial surface of the GBM, and foot process effacement (Fig. 3). The percentage of GBM displaying this lesion increases progressively with age in boys with XLAS [105]. Females with XLAS display a range of GBM alteration, from focal GBM attenuation to diffuse thickening and basket weaving, and there is no consistent correlation of GBM findings and age [105].

Routine immunofluorescence is normal or shows nonspecific immunoprotein deposition. Because disease-causing mutations result in abnormal expression of α3α4α5(IV) and α5α5α6 (IV) networks in basement membranes in most Alport patients, specific immunostaining for type IV collagen α chains is useful for both diagnosis and differentiation of XLAS and ARAS [106] (Figs. 4 and 5). Expression of the α3(IV), α4(IV), and α5(IV) chains is completely absent in ~80% of XLAS males, and 60–70% of females with XLAS exhibit mosaic expression of these chains [106] (Fig. 6). In most patient with ARAS, GBM is nonreactive with antibodies to the α3(IV), α4(IV), and α5(IV) chains, and Bowman's capsules and tubular basement membranes are also negative for the α3(IV) and α4(IV) chains [107] (Fig. 5). However, immunostaining for α5(IV) chains in Bowman's capsules and tubular basement membranes is present, because in these basement membranes expression of α5α5α6(IV) networks is preserved. It is important to note that altered immunostaining for the α3(IV)-α6(IV) chains in patients with XLAS and ARAS is not age-dependent. Therefore, this method can provide diagnostic information even in patients who are too young to display characteristic abnormalities in GBM ultrastructure.

Normal epidermal basement membranes (EBM) express the α5α5α6(IV) network but not the α3α4α5(IV) network. EBMs show negative staining for α5(IV) chains in about 80% of

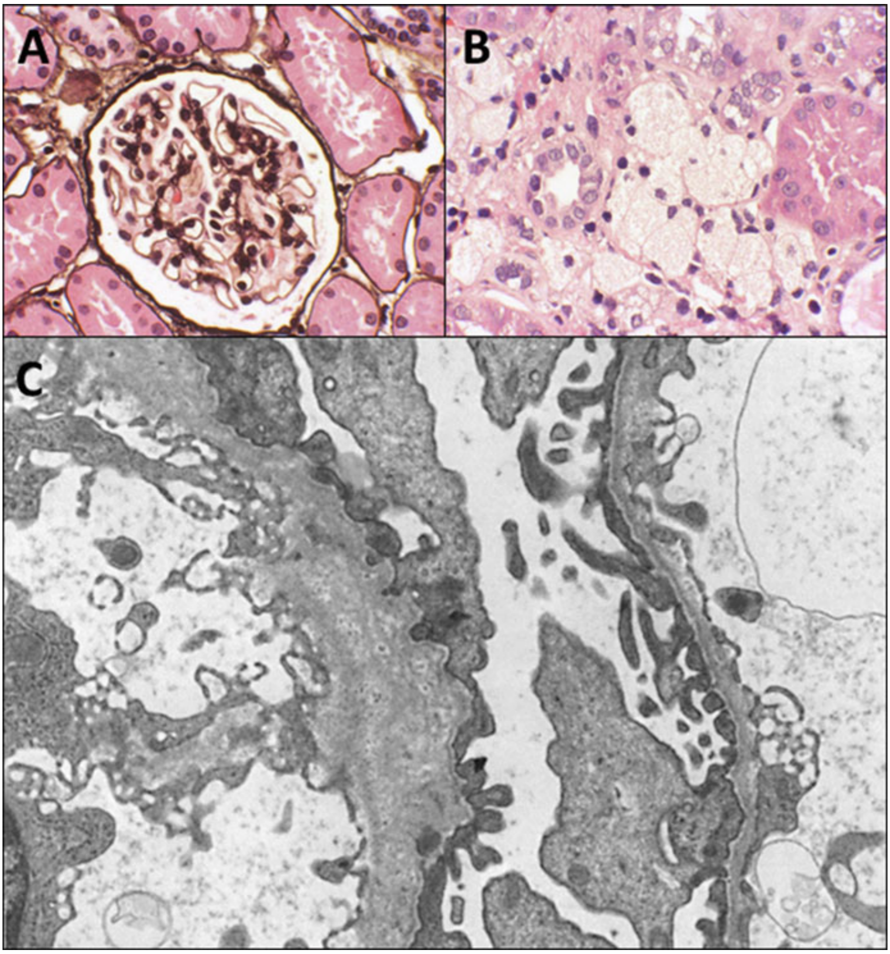

Fig. 3 (**a**) 9-year-old boy with proteinuria, hematuria, family history of Alport syndrome. The glomeruli appeared unremarkable by light microscopy (Jones' silver stain, ×400). (**b**) Multifocal interstitial foam cells, a finding that may be present even in early Alport syndrome due to longstanding low-grade proteinuria, and also seen in patients with marked proteinuria due to other causes. This is the same patient as in A, with minimal interstitial fibrosis (hematoxylin and eosin, ×400). (**c**) Alport syndrome electron micrograph. Right: Thin GBM. Left: Thickened GBM showing splitting and lamellation of the lamina densa with effacement of podocyte foot processes. Lead citrate and uranyl acetate stain (×11,250). XLAS males, and mosaic expression of α5(IV) is observed in 60–70% of XLAS females, allowing diagnosis of XLAS by skin biopsy [108, 109]. Skin biopsy is not useful for diagnosis of ARAS, since expression of the α5α5α6 (IV) network in EBM is normal [107]. Skin biopsy has fallen out of favor for diagnosis of Alport syndrome given these limitations as well as the increased accessibility of genetic testing.

Diagnostic Considerations

Accurate diagnosis of Alport syndrome and differentiation of this condition from other causes of familial and sporadic glomerular hematuria are based upon careful clinical evaluation, reliable pedigree data and thoughtful consideration of the relative merits of kidney biopsy and/or genetic testing. In a child with isolated hematuria and no

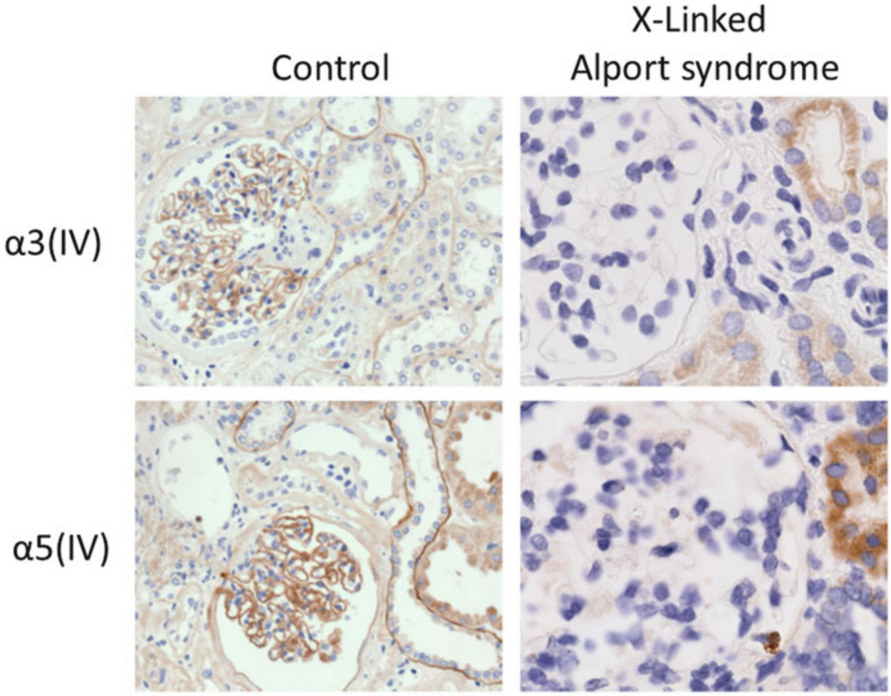

Fig. 4 Immunohistochemistry of normal kidney and male with X-linked Alport syndrome. In the normal kidney, α3(IV) and α5(IV) are present within the GBM. In patient with Alport syndrome, α3(IV) and α5(IV) are absent. (Images courtesy of Dr. Jan Ulrich Becker)

family history of hematuria, the differential diagnosis of glomerular hematuria includes Alport syndrome, IgA nephropathy, membranoproliferative glomerulonephritis, membranous nephropathy, lupus nephritis, postinfectious glomerulonephritis, and IgA vasculitis. Associated clinical findings (e.g., rash, arthritis) or laboratory findings (e.g., hypocomplementemia) will suggest diagnoses other than Alport syndrome in many of these patients. In a child with isolated hematuria and a positive family history of hematuria in the absence of a history of ESKD, two rare causes of familial hematuria associated with macrothrombocytopenia, Epstein and Fechtner syndromes, can be excluded if the platelet count is normal. Familial IgA nephropathy [110] and membranoproliferative glomerulonephritis [111] are uncommon causes of familial hematuria.

While results of hearing evaluation are likely to be normal in young children with Alport syndrome, audiometry may be very useful in children over 6–8 years of age, especially boys. Ophthalmologic assessment may also provide valuable information, although ocular lesions are more prevalent in Alport patients with advanced disease and less likely to be present in the population of young patients in whom differential diagnosis of hematuria may be more difficult.

Tissue studies can complement clinical and pedigree information that is insufficient to clearly differentiate Alport syndrome from other diagnoses. Skin biopsy with immunostaining for the α5(IV) chain, as described above, may be diagnostic, especially when clinical and pedigree data strongly suggest a diagnosis of XLAS. Normal expression of the α5(IV) chain in epidermal basement membrane can be explained in several ways: (1) the patient has XLAS, but his or her *COL4A5* mutation does not abolish α5(IV) expression; (2) the patient has a form of Alport syndrome (ARAS or ADAS) in which expression of α5(IV) in epidermal basement membranes is not affected; or (3) the patient does not have Alport syndrome. While skin biopsy is useful only if it

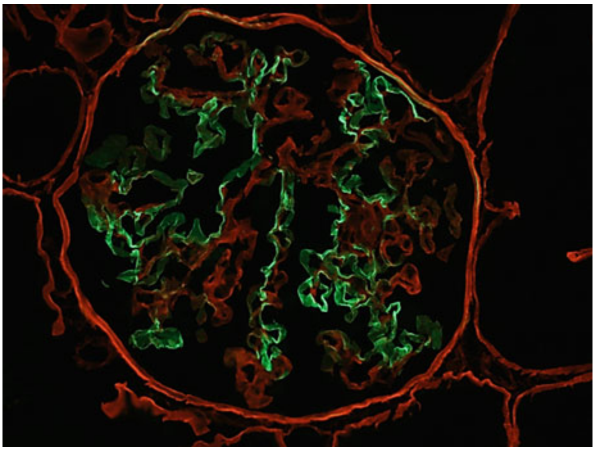

Fig. 6 Immunofluorescence microscopy of glomerulus from women with X-linked Alport syndrome. Red identifies α2(IV) in the GBM. Green identifies α5(IV) in a mosaic pattern in the GBM reflective of X-inactivation. (Image courtesy of Dr. Lihong Bu)

provides definitive confirmation of a diagnosis of XLAS, renal biopsy carries the advantage of enabling the diagnosis of XLAS, ARAS and non-Alport kidney disease, particularly if type IV collagen immunostaining is applied.

Mutation detection rates of 80–90% are attainable in males with XLAS using direct sequencing of *COL4A5* [112]. Comparable data for detection of *COL4A3* and *COL4A4* mutations in patients with ARAS are lacking. Next-generation sequencing (NGS) allows for rapid simultaneous analysis for mutations in *COL4A3*, *COL4A4*, and *COL4A5* [70]. The genetic testing approach may vary based on the level of suspicion of a diagnosis of Alport syndrome. When suspicion is high, NGS of *COL4A3*, *COL4A4*, and *COL4A5* is indicated. When suspicion of a diagnosis of Alport syndrome is moderate or low, a broad NGS panel including focal segmental glomerulosclerosis causative genes or even whole exome sequencing should be considered (82). Commercially available genetic testing for mutations in *COL4A3, COL4A4*, and *COL4A5* is available in many countries. Since the finding of a heterozygous mutation in *COL4A3* or *COL4A4* cannot guarantee a benign prognosis [69, 70, 113, 114], the need for follow-up examination of such patients is vital.

Treatment

The goal of treatment in patients with Alport syndrome is to slow the progression of kidney disease and delay the need for renal replacement therapy. Inhibition of the renin-angiotensin system (RAS) is the mainstay of treatment. These agents reduce glomerular hyperfiltration and inhibit profibrotic pathways within the kidney.

RAS blockade in mouse models of Alport syndrome leads to a doubling of lifespan in animals treated early in their disease course [115]. Uncontrolled studies in patients with Alport syndrome have shown that RAS blockade can transiently reduce proteinuria [116, 117]; however, it remains unclear if this can predict loss of glomerular filtration rate (GFR). Subgroup analysis of 30 children with Alport syndrome in a larger multicenter, randomized, double-blind study comparing losartan with placebo or amlodipine in proteinuric children demonstrated a significant reduction in proteinuria in the losartan-treated group [118]. An extension of this study showed comparable efficacy of either enalapril or losartan in reducing proteinuria in children with Alport syndrome [119]. A retrospective review of 79 children with Alport syndrome showed a significant decrease in proteinuria over the first 2 years of treatment that was stable in years 3–5 [120].

Two retrospective registry studies show the strongest evidence for treatment with RAS blockade. A report from the European Alport Registry, which included 283 patients followed over 20 years, compared kidney outcomes in Alport syndrome patients treated with RAS inhibition starting at various disease time points: microalbuminuria, proteinuria, or chronic kidney disease (CKD) stages III–IV [121]. This study demonstrated a delay in renal replacement therapy by 3 years in the treated CKD group and by 18 years in the treated proteinuric group [121]. A second report from the Japanese Alport Registry reported outcomes in 430 males with XL Alport syndrome [76]. They reported that patients treated with RAS inhibition reached ESKD an average of 22+ years later than those who were untreated. There were benefits to treatment for patients with both truncating and non-truncating mutations. A randomized controlled trial of ramipril versus placebo in children with early Alport syndrome (hematuria alone or albuminuria between 30–300 mg/g) was unfortunately unable to recruit sufficient patients, and an additional open-label treatment arm and retrospective control arm were added to enhance interpretation of results [122]. Over 6 years of follow-up, there was a 50% decreased risk of proteinuria progression in the ramipril-treated group; however, results were not statistically significant. Importantly, no safety issues were identified in over 200 patient years of treatment.

Clinical practice guidelines have been developed to guide treatment of patients with Alport syndrome, including heterozygous females [123]. Treatment with angiotensin converting enzyme inhibitors or angiotensin receptor blockers should be initiated for boys with XL Alport syndrome or boys and girls with AR Alport syndrome at the time of diagnosis after thorough discussion of risks and potential benefits of treatment with parents. Treatment is recommended for children with AD Alport syndrome or girls with XL Alport syndrome when they develop any albuminuria.

A number of novel treatment strategies have been shown to slow progression of kidney disease in mouse models of Alport syndrome including transforming growth factor beta 1 inhibition [124], chemokine receptor 1 suppression [125], administration of bone morphogenic protein-7 [126], blockade of matrix metalloproteinases [127], microRNA-21 inhibition [128], endothelin-1 receptor antagonism [129], and bone marrow transplantation [130, 131]. Clinical trials are ongoing testing an anti-microRNA-21 agent (NCT02855268) and the anti-inflammatory agent bardoxolone (NCT0309185) in patients with Alport syndrome. No treatments are currently available to ameliorate the progression of hearing loss in patients with Alport syndrome.

Restoration of the GBM in patients with Alport syndrome is also a potential strategy for treatment or even potential cure. Gene-editing technologies such as CRISPR-Cas9 or exon-skipping therapies may provide additional options for patients in the future [40, 132, 133]. Protein replacement strategies could also be employed to directly target recombinant type IV collagen to the GBM. This approach has been successfully utilized in a mouse model of Pierson syndrome where injection with recombinant laminin 521 delayed onset of proteinuria [134]. Finally, chemical chaperone-based therapy was shown to enhance deposition of COL4A5 in a preclinical study [135].

Transplantation

Patients with Alport syndrome typically do well after kidney transplantation with similar or better graft survival than matched controls [136, 137] Two issues require the special attention of transplant physicians involved in the care of patients with Alport syndrome. First, evaluation of potential related donors must identify affected individuals who may have heterozygous mutations in type IV collagen genes who may be at risk for progressive CKD. A case series of women with Alport syndrome who donated their kidney showed that new-onset hypertension, proteinuria, and GFR decline were common after donation [138]. Second, posttransplant monitoring must allow early diagnosis of posttransplant anti-GBM nephritis, a complication of transplantation that is unique to Alport syndrome.

Anti-GBM nephritis occurs in 1–3% of men with X-linked Alport syndrome after transplantation [139]. The onset of anti-GBM nephritis typically occurs during the first year after transplantation and usually results in irreversible graft failure within weeks to months of diagnosis. There is a high rate of recurrence in subsequent allografts. In XLAS males, the primary target of anti-GBM antibodies is the α5(IV) chain [140, 141]. Females with XLAS who require transplantation are at little or no risk of developing anti-GBM nephritis. However, both males and females with ARAS can develop anti-GBM nephritis after transplantation. The α3(IV) chain is the primary target of anti-GBM antibodies in ARAS patients [140, 142]. Although both Goodpasture autoantibodies and anti-GBM antibodies from transplanted Alport patients target the carboxyterminal noncollagenous (NC1) domain of the α3(IV) chain, they target separate and distinct epitopes [143].

Kidney transplant biopsy with routine immunofluorescence should be performed early in the evaluation of Alport patients who develop hematuria or increased creatinine after transplantation or if circulating anti-GBM antibodies are detected. Anti-GBM nephritis after kidney transplantation has been treated with cytotoxic therapy and plasmapheresis, although such therapy has been unsuccessful in the majority of reported patients.

Pierson Syndrome

The association of congenital nephrotic syndrome with eye abnormalities in siblings was first described by Pierson in 1963 [144]. This condition is inherited in an autosomal recessive manner and accounts for ~2.5% of congenital and infantile nephrotic syndrome.

Genetics

The gene for Pierson syndrome was mapped to chromosome 3p14–p22 and identified as *LAMB2*, the gene encoding the laminin β2 chain, by Zenker and colleagues in 2004 [46]. Subsequent reports indicate that *LAMB2* mutations may be associated with isolated congenital nephrotic syndrome and with mild variants of Pierson syndrome [145, 146]. The absence of the laminin β2 chain in transgenic mice results in massive proteinuria along with retinal and neuromuscular abnormalities [147]. In these mice, proteinuria precedes the appearance of podocyte abnormalities, suggesting that the GBM contributes to the barrier function of the glomerular capillary wall. Genotype influences the phenotype in individuals with *LAMB2* mutations. Truncating or splice site mutations are more likely to be associated with complete Pierson syndrome, whereas missense mutations or small deletions are more likely to be associated with the absence of neurologic abnormalities and later onset of kidney disease [146, 148].

Clinical Features

In the earliest reports of Pierson syndrome, affected infants died within the first year of life with ESKD. Subsequent reports of additional patients described variable abnormalities on fetal ultrasound, including kidney enlargement and hyperechogenicity, oligohydramnios, placental enlargement, and/or pulmonary hypoplasia [46, 149]. Infants surviving to term exhibited congenital nephrotic syndrome accompanied by ocular globe enlargement (buphthalmos) with reduction in the size and reactivity of pupils (microcoria). Additional ocular findings in some patients included cataract, posterior rupture of the lens capsule, and retinal abnormalities. Some affected children have also been found to have muscular hypotonia, central nervous system hemangiomas, and genital abnormalities [150, 151].

Pathology

Children with Pierson syndrome demonstrate kidney biopsy findings of diffuse mesangial sclerosis and diffuse GBM abnormalities [152]. The GBM demonstrates irregular thick and thin zones on both sides of the lamina densa and may have lamellation and corrugation.

MYH9-Related Disorders

MYH9-related disorders are rare autosomal dominant conditions which may have similar clinical features as Alport syndrome including hematuria, progressive CKD, and sensorineural deafness [153]. Historically, four separate syndromes with variable phenotypes were identified that were all found to be caused by mutations in *MYH9*: Epstein syndrome, Fechtner syndrome, Sebastian syndrome, and May-Hegglin anomaly. Given the wide variability in phenotype in patients with *MYH9* mutations that do not always fit neatly into these syndromic categories, the term *MYH9*-related disease is preferred.

Genetics

MYH9 encodes nonmuscle myosin heavy chain IIA (NMMHC-IIA). NMMHC-IIA is expressed in podocytes [154], but the mechanism by which mutations in this protein might adversely affect podocyte function is unknown. It is hypothesized that *MYH9* mutations may disrupt the ability of the podocyte to produce and incorporate extracellular matrix proteins into the GBM [155]. Members of the same family may have different phenotypes.

Clinical Features

Kidney involvement occurs in about 30% of patients and consists of proteinuria with or without hematuria and progressive CKD. Most patients with *MYH9* mutations have thrombocytopenia and giant platelets which may lead to clinical bleeding disorders and limit the ability to perform kidney biopsy. In addition, the mutated NMMHC-IIA forms aggregates in leukocytes that are visible as Döhle-like bodies. Sensorineural hearing loss may present between the 1st and 6th decades of life [156], and early-onset cataracts can also be seen.

Pathology

In some patients with *MYH9*-related disease, ultrastructural changes in the GBM resemble those of Alport syndrome [157, 158]. EM may demonstrate glomerular GBM thickening, splitting, or attenuation [155]. However, glomerular expression of type IV collagen α3, α4, and α5 chains is normal in these patients [158]. Light microscopy may show mesangial proliferation, segmental glomerulosclerosis, and tubulointerstitial disease [155].

Treatment

Case series have described a reduction in proteinuria in patients with *MYH9* mutations treated with renin-angiotensin system blockade [159, 160].

Nail-Patella Syndrome

Nail-patella syndrome (NPS) is a rare autosomal dominant disorder characterized by dystrophic nails, hypoplasia or absence of the patellae, dysplasia of the elbows and iliac horns, and kidney disease [161, 162]. Affected individuals may also exhibit glaucoma and sensorineural deafness [163, 164]. The disorder affects about 1 in 50,000 individuals. Kidney involvement occurs in 30–40% of patients.

Genetics

Heterozygous mutations in the LIM homeodomain transcription factor gene *LMX1B* cause NPS [165, 166]. Mutations in the homeodomain of LMX1B protein and female sex may confer an increased risk of kidney involvement [164].

LMX1B protein is specifically expressed in glomerular podocytes, beginning at the S-shaped body stage of glomerular development [167]. Lmx1b-null mice exhibit marked reduction in GBM expression of the α3 and α4 chains of type IV collagen and the slit diaphragm proteins podocin and CD2AP [168–170]. However, changes in expression of these putative targets of LMX1B were not observed in the kidneys of patients with NPS nephropathy [171]. LMX1B was found to be essential for the maintenance of differentiated podocytes in adult kidneys through effects on actin cytoskeletal organization [172]. Mutations in *LMX1B* have also been described in patients with autosomal dominant focal segmental glomerulosclerosis without extrarenal involvement [173].

Clinical Features

Kidney. Less than half of NPS patients have clinically apparent kidney disease [174]. Symptoms including mild proteinuria with or without microscopic hematuria typically appear in adolescence or young adulthood. Occasional patients develop nephrotic syndrome and hypertension. The nephropathy is typically mild, with about a 5–10% risk of progression to ESKD. Marked differences in the severity of the nephropathy can be observed in related patients, suggesting the influence of superimposed factors. As with other glomerular disorders, proteinuria appears to be a risk factor for progression [175].

Nails. Nail abnormalities occur in over 90% of patients and are usually apparent from birth [176]. Fingernails, especially on the thumb and index finger, are more severely affected than toenails. The nails may be absent or dystrophic with discoloration, koilonychias, longitudinal ridges, or triangular lunulae.

Skeletal Defects. Over 90% of NPS patients exhibit aplasia or hypoplasia of the patellae [176]. Associated symptoms may include knee pain, effusions, dislocations, and osteoarthritis. Dysplasia of the elbows occurs in over 90% of patients [176]. Anomalies such as hypoplasia of the radial head with dislocation, posterior processes at the distal ends of the humeri, hypoplasia of the olecranon, and elongation of the neck of the radius may be associated with mild to severe limitation in extension, pronation, and supination of the forearm. About 80% of patients display osseous processes projecting posteriorly from the iliac wings, known as iliac horns, which are pathognomonic for NPS [176].

Pathology

The nephropathy of NPS has no specific features by light microscopy or routine immunofluorescence [177]. Focal segmental glomerulosclerosis and nonspecific deposits of IgM and C3 may be observed, depending on the severity of renal involvement. Characteristic lesions are observed by electron microscopy [178, 179]. With standard staining techniques, the GBM exhibits multiple lucencies, imparting a “moth-eaten” appearance. Staining with phosphotungstic acid reveals clusters of cross-banded collagen fibrils within these lucent areas with a periodicity of about 65 nm (Fig. 7). These collagen fibrils have been observed in NPS patients with no clinically evident renal disease, and there is no correlation between the extent of GBM changes and patient age, severity of proteinuria, or degree of kidney disease [180, 181]. Conversely, kidney involvement in patients with LMX1B mutations has been described without the classic features described above [182].

Treatment

There is no specific therapy for NPS renal disease. Kidney transplantation has been carried out successfully, and recurrence of renal disease apparently did not recur. Selection of living donors must be performed with care, since NPS is an autosomal dominant disorder.

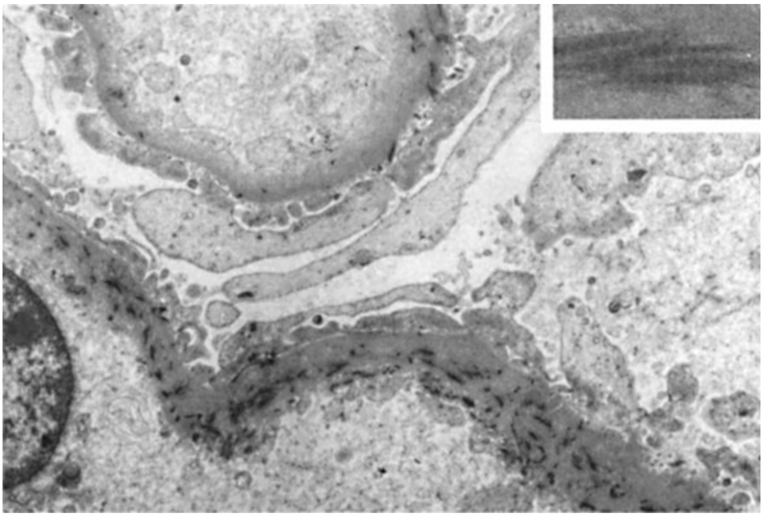

Fig. 7 Electron microscopy of nail-patella syndrome. Irregular distribution of fibrillar collagen within the GBM. Phosphotungstic acid stain (×10,500). Inset shows the typical periodicity of interstitial collagen (×48,000)

Abstract

Nephrotic syndrome is among the most common chronic kidney diseases of childhood. The condition is primary or idiopathic in more than 90% cases. Therapy with prednisone results in complete remission of proteinuria in ~90% patients, termed steroid-sensitive nephrotic syndrome (SSNS). Approximately, 70% patients with SSNS relapse, and about 50% show frequent relapses or steroid dependence that requires careful therapy with steroid sparing agents. The aim of this therapy is to prevent complications of the disease and minimize the side effects of corticosteroids and other medications. SSNS is a self-limiting illness with majority of patients outgrowing the disease by puberty. However, a small but significant proportion of patients show persistence of the illness into adulthood.

Introduction

Nephrotic syndrome, characterized by edema, heavy proteinuria (>1 g/m^2/day; >40 mg/m^2/h; spot urine protein/creatinine ratio >200 mg/mmol), and hypoalbuminemia (serum albumin <3 g/dL), is among the most common chronic kidney diseases of childhood [1]. The condition has an annual incidence ranging from 1.2 to 16.9 per 100,000 children. While nephrotic syndrome is usually primary or idiopathic, evaluation may reveal an underlying systemic illness in 5–10% patients. Therapy with prednisone results in complete remission of proteinuria in 85–90% patients, termed steroid-sensitive nephrotic syndrome (SSNS). While approximately 50% patients with SSNS have frequent relapses or steroid dependence, and 3–10% show late steroid resistance, their long-term outcome is satisfactory. The prognosis is less favorable in those that fail to respond to corticosteroid treatment (steroid resistant). This chapter discusses the evaluation, management, and outcomes of patients with SSNS.

Historical Background

Hippocrates connected dropsy (edema) with kidney disease almost 2500 years ago and noticed that urine produced by people with dropsy showed bubbles [2]. In the fifteenth century, Cornelius Roelans regarded swelling of the child's whole body as one of 52 distinguished childhood diseases. In 1722, Theodore Zwinger III (Basel) made a detailed and accurate description of the signs and symptoms of nephrotic syndrome in children with hydrops (whole-body edema) and linked the condition to a problem in the kidney tubules. Measuring urine protein became available in the eighteenth century. Domenico Cotugno connected proteinuria and edema, and in 1827, Richard Bright described a triad of edema, proteinuria, and kidney disease. In the nineteenth century, histopathological examination was made in postmortem kidney specimens from patients with syphilis, who most likely had membranous nephropathy. Microscopic techniques of that period did not identify a glomerular lesion in such specimen, and physicians assumed that the condition resulted from degenerative changes in the kidney tubules. As a result, in 1905, Friedrich von Muller used the term "nephrosis" to distinguish a noninflammatory glomerular lesion in nephrotic patients with syphilis, from the inflammatory "nephritis" in other conditions. Hence, the term "pure nephrosis" or minimal change nephropathy was established. The term "syndrome of nephrosis" or "nephrotic syndrome" was introduced in 1931 by Henry Christian and Louis Leiter, who noted similarities between primary and secondary forms of the severe proteinuric disease with edema.

The invention of the electron microscope by Max Knoll and Ernst Ruska in 1931 allowed the detection of the characteristic ultrastructural changes of the glomerular podocyte, described as fusion or effacement of the foot processes. In the 1950s and 1960s, routine use of percutaneous kidney biopsy allowed the collection of data demonstrating different histologic lesions in adults with nephrotic syndrome. By contrast, minimal change disease (MCD) was the chief histologic diagnosis in patients younger than 6-years-old treated for nephrotic syndrome at the Guy's Hospital in London before 1970 [2]. In almost all of these patients, proteinuria resolved in response to corticosteroids within 4 weeks. Thus, the therapeutic response to corticosteroids became the basis of the term "steroid-sensitive nephrotic syndrome."

A collaborative effort by the International Study of Kidney Disease in Children (ISKDC) and Arbeitsgemeinschaft fur Padiatrische Nephrologie (APN) in 1960–1970 established the therapeutic approach to childhood nephrotic syndrome [3–7]. Studies were conducted, between 1967 and 1974, at 24 centers in North America, Europe, and Asia that enrolled patients from 12-weeks to 16 years of age. All patients had percutaneous kidney biopsy before therapy. Of the 521 patients, 76.6% had MCD, 7.5% had membranoproliferative glomerulonephritis (MPGN), and 6.9% had focal segmental glomerular sclerosis (FSGS). Patients were treated with prednisone 60 mg/m^2 (maximum 80 mg) daily for 4 weeks, followed by 40 mg/m^2 daily on 3 consecutive days out of seven for 4 weeks. They concluded that therapeutic response to steroids was useful for initial evaluation and therapy, because most patients had MCD and most were sensitive to corticosteroids. In contrast, patients with non-minimal lesions (MPGN or FSGS) were more commonly resistant to corticosteroids. Hence, response to steroids is widely adopted for the initial management and prevents unnecessary kidney biopsies in most children with nephrotic syndrome [8, 9].

Furthermore, the prediction that a patient who fails to respond has a glomerular lesion other than MCD would be incorrect in about one-fourth of all children with nephrotic syndrome, and as many as one-half of patients ≤6 years of age [7]. For these patients, a pathologic diagnosis is recommended. Since the 1980s, many centers have reported increased frequency of FSGS in children of different ethnicities or primary corticosteroid resistance [10–16]. Because the single-center studies used different corticosteroid regimens and FSGS can be indistinguishable from MCD during the early stage, it is not easy to compare the results of these reports with the results of the ISKDC studies [17]. Nevertheless, therapeutic response to corticosteroids remains a valid approach for the initial management of children with nephrotic syndrome [18].

Etiology

Nephrotic syndrome is caused by a glomerular injury that alters the glomerular filtration barrier and leads to urinary loss of plasma proteins.

Mechanisms of Proteinuria

Proteinuria in nephrotic syndrome results from increased passage of proteins across the glomerular capillary wall that exceeds the proximal tubular epithelial cells' absorptive capacity. Many discoveries have improved the understanding of how a normal glomerular capillary wall restricts plasma proteins from entering into the Bowman's space. It is generally accepted that the molecular size, electrical charge, and steric configuration affect the transglomerular passage of proteins.

The glomerular capillary wall comprises the fenestrated endothelial cells, glomerular basement membrane (GBM), and the dynamic structure between interdigitated podocyte foot processes, called the glomerular slit diaphragm (SD). The endothelial cells contain an anionic glycocalyx on the cell surface and form a fenestrated layer on the luminal side of the GBM. Despite the large pore size of the fenestrae (375–400 Angstrom (Å)), the endothelial cells can form an electrostatic barrier for negatively charged proteins, including albumin having a radius of 36 Å [19, 20]. Recent studies in animal models have confirmed the importance of endothelial cells and the glycocalyx in the selectivity of the filtration barrier [21, 22]. Another line of evidence for the role of endothelial cells in the filtration barrier function comes from animal studies showing that inhibition of vascular endothelial growth factor (VEGF) leads to endothelial cell dysfunction and proteinuria [23, 24].

The GBM is an acellular network formed by a scaffold of cross-linked collagen IV, laminins, and proteoglycans. GBM plays a central role in the size- and charge-selectivity with a variable contribution of each component. Type IV collagen provides mainly structural support to the glomerular capillary wall and contributes relatively less to the selectivity of the filtration barrier. This conclusion was derived from the usually mild proteinuria observed in patients with Alport syndrome [25]. Proteoglycans contain negatively charged glycosaminoglycan side chains. Heparan sulfate proteoglycans (HSPG) are responsible for the anionic charge of the GBM, and their role in the filtration barrier is widely accepted [26]. However, recent studies in murine models have questioned the role of HSPG [27–29]. By contrast, laminins were shown to play an essential role in the GBM organization and the filtration selectivity. Laminins are heterotrimeric proteins that self-assemble into a network. Animal studies show that laminin-521 is crucial for a filtration barrier [30–32]. Mutations in *LAMB2* cause Pierson syndrome, characterized by congenital nephrotic syndrome and ocular abnormalities [33].

The final filtration barrier with a functional size-selectivity of 40–45 Å resides at the glomerular SD and the podocyte–GBM interface. Podocytes are anchored to the GBM by transmembrane proteins, including integrins and tetraspanins [19]. The most abundant in podocytes, integrin α3β1, interacts with the GBM laminin-521 providing a vertical force for podocyte adhesion. Tetraspanins interact with integrins in specialized cell membrane microdomains. The interaction between tetraspanin CD151 and integrin α3β1 provides a horizontal force strengthening the podocyte adhesion to GBM. In addition to transmembrane proteins, other cellular adaptors, including integrin-linked kinase, regulate the filtration barrier at the podocyte–GBM interface. Knockout of the above proteins in animal models disrupts the podocyte–GBM interface and leads to podocyte detachment and proteinuria. These studies confirm that podocyte dysfunction plays a central role in the development of proteinuria in nephrotic syndrome.

The glomerular SD is a highly specialized junctional complex with some features of other type junctions and some unique properties. It is formed by the transmembrane protein networks, their intracellular adaptors and scaffolding proteins, and the noncontractile actin fibers that interconnect with contractile actin cables within podocyte cell bodies and major processes [19, 34, 35]. The SD contains the adherens junction components P-cadherin, β-catenin, and FAT, the tight junction members ZO-1, JAM-A, occludin, and cingulin, as well as proteins expressed in the podocytes, including nephrin, nephrin-like (neph) 1, and podocin [36–40]. The unique composition of the SD is central to its function, and loss of its specificity ultimately leads to proteinuria [41]. The characteristics of the glomerular SD molecular sieve are defined by dynamic protein–protein interactions, membrane trafficking, and signaling in the inside-out and outside-in directions [20, 42]. Understanding of the regulation of SD function is still incomplete, and new data are added each year [43].

Mechanisms of Glomerular Injury

The etiology of SSNS is unknown. It is suggested that SSNS may result from activation of the immune system in response to an infection [44]. The clinical observation that manifestations of SSNS frequently follow an upper respiratory infection seems to support such a conclusion. Clinical observations that patients initially responsive to corticosteroids may become resistant, while those with initial resistance may later show partial response suggest that steroid sensitivity, dependency and resistance represent a spectrum of a single disease [45]. It seems that the classification of nephrotic syndrome based on the response to corticosteroids, while useful therapeutically, is not etiologic and does not inform about the mechanism of glomerular injury. The presence of circulating factor(s) responsible for proteinuria has been hypothesized, but none of the candidate molecules have been confirmed [46].

Genetic Basis

Epidemiologic studies suggest that genetic risk have a role in the pathogenesis of SSNS. For example, 3% of children with SSNS have a first-degree relative with the same disease [47]. Ethnic background affects the incidence and severity of INS, with Black and South Asian children having a higher incidence than White children [15, 48]. Black children are also more likely to show corticosteroid resistance and FSGS compared to White children [15, 49].

While Mendelian inheritance has been shown in up to 30% of cases of steroid-resistant nephrotic syndrome (SRNS), it has not been confirmed in SSNS. To date, all of the genetic variants proposed to cause Mendelian SSNS can be classified as variants of uncertain significance, and many of them are shown to occur at high frequency in the general population [50, 51]. Most of the variants reported in the literature are from small, single-family studies and have not been validated in independent larger cohorts. By contrast, familial clustering of SSNS is well recognized [52]. The polygenic pattern suggests that genetic variations, perhaps together with environmental factors, may underline the susceptibility to SSNS but are not sufficient to cause the condition. How the complex polygenic pattern affects the susceptibility to SSNS remains incompletely understood.

The vast majority of relevant genetic variants identified in complex disease lie outside coding regions [53, 54]. Many of those are found to be in areas relevant for gene regulation, such as promoters and enhancers. Additionally, complex interactions between these variants are thought to increase the risk of disease [53]. Genome-wide association studies (GWAS) using candidate gene approaches found the strongest association within the HLA genetic region, HLA-DR/DQ, specifically in and around HLA-DQA1 and HLADQB1 [44, 55]. The exome-wide association study, which was not limited to a selection of genes, identified four variants (rs1129740, rs9273349, rs1071630, and rs1140343) in the HLA-DQA1/HLA-DQB1 locus in association with SSNS in a South Asian cohort [56]. Thus, GWAS has confirmed the longstanding observation that the immune system plays a critical role in SSNS [57–61]. An increased number of risk alleles in the HLA-DR/DQ region (rs1063348) and (rs28366266) was associated with an increased SSNS risk as well as decreased age at onset of disease. Additionally, the lead variant (rs1063348) around HLA-DQB1 was associated with significantly decreased expression of HLA-DRB1, HLADRB5, and HLA-DQB1 in glomeruli of children with SSNS [61]. Additional support for the involvement of the HLA-DR/DQ region in SSNS came from a GWAS investigating a large European cohort [60]. GWAS in Japanese SSNS patients confirmed the association with HLA-DR/DQ in a different ethnicity [58, 59]. The above findings underline the central role of the immune system in SSNS, but also demonstrate a complex mechanism of SSNS.

The variants in the HLA region are frequently linked together, and the composite haplotype HLA-DQA1*02:01, HLA-DRB1*07:01, and HLADQB1*02 are associated with the strongest risk of SSNS [60, 61]. The same haplotype was identified in a group of South Asian children as a risk for SSNS [62]. Conversely, HLADQA1*01, HLA-DQA1*01:03, and HLA-DRB1*13 appear to be protective in the European cohort and also in the South Asian cohort. The relevance of these haplotypes in the pathogenesis of SSNS is highlighted by preservation across different ethnic groups. By contrast, the common risk haplotype of the European and South Asian population (HLA-DQA1*02:01; HLA DRB1*07:01; HLA-DQB1*02) was not replicated in the Japanese cohorts [58, 59]. The haplotype associated with the strongest risk for the disease was HLA-DRB1*08:02, DQB1*03:02, and the haplotype with the strongest protective association was HLA-DRB1*13:02, DQB1*06:04. These specific haplotypes are extremely rare in Europeans in contrast to the Japanese population [44, 63]. Variants outside of the HLA region have also been identified as a risk for SSNS. For example, the gene *BTLN2* (butyrophilin-like 2) plays a role in the regulatory T cell differentiation, and its missense variant is associated with SSNS in different cohorts [44, 61]. The involvement of different HLA alleles and regions outside of the HLA in different ethnic populations may be explained, at least in part, by diverse infectious triggers in different geographic regions.

Immune Mechanism

The role of the immune system in the pathogenesis of idiopathic nephrotic syndrome (INS) is poorly understood despite evidence of T-lymphocyte dysregulation, local cytokine release, and a hypothetical glomerular permeability factor. In 1974, Shaloub et al. proposed that lipoid nephrosis results from a systemic dysregulation of T-lymphocytes [64]. The authors hypothesized that a T-lymphocyte-derived systemic factor acts on the GBM and increases glomerular permeability. This hypothesis was supported by animal studies showing that supernatants of T-cell hybridoma lines produced from patients with MCD induced foot process effacement and proteinuria [65]. Since then, many studies have supported the role of T-lymphocytes in the pathogenesis of MCD [66]. Expressly, the prevalence of CD8+ T-suppressor cells was noted in an animal model of nephrotic syndrome, while type 2 T-helper (Th2) cell cytokines were elevated in patients with MCD. However, of all the Th2 cytokines, only IL-13 overexpression induced foot process effacement and proteinuria in animal models [67]. Evidence from other studies, supported by some clinical observations, indicated reduced function of regulatory T-cells [66, 68]. Thus, a complex network, rather than a single factor, may contribute to the pathogenesis of MCD.

B-lymphocytes may have a role in the pathogenesis of MCD, based on histologic and hematologic evidence, successful treatment with an anti-CD20 approach, and the involvement of B-cell-derived IL-4 in podocyte injury [64, 69, 70]. There is also evidence against the role of B-cells in the pathogenesis of MCD. First, there is little or no Ig deposition on renal biopsy in MCD. Second, the CD20+ B-cell depletion by rituximab cannot be used as evidence for B-cell dysregulation because rituximab also binds in podocytes to a potential second receptor, sphingomyelin phosphodiesterase acid-like 3b (SMPDL3B) [71]. Rituximab binding to SMPDL3B was proposed to prevent podocyte injury by maintaining an intact podocyte cytoskeleton [72]. Third, some patients undergo prolonged remission after rituximab despite reconstitution of total B-cells [73]. The reconstitution of switched memory B cells and not the total B-cell population predicted relapse in children with frequently relapsing or steroid-dependent nephrotic syndrome [74]. Targeting B-cells with CD20-depleting agents such as rituximab may affect costimulatory pathways involved in T-cell activation and modify other cell lineages, such as Th17 implicated in the pathogenesis of INS [75, 76]. Finally, relapse of INS during B-cell depletion after receiving rituximab suggests the presence of diverse pathophysiological mechanisms in different forms of nephrotic syndrome [77].

Podocyte-Specific Pathways

Response to corticosteroids is thought to result from its immunosuppressive effects, although studies suggest that glucocorticoids might also have a direct nonimmune function mediated by Kruppel-like factor 15 (KLF15), targeting podocytes [78, 79]. Preclinical studies suggesting the role of podocyte-specific factors in the pathogenesis of SSNS need validation. For example, subsequent studies failed to confirm the pathogenic role of B7–1 (CD80) in MCD or FSGS [80]. Another protein implicated in the pathogenesis of MCD, hemopexin, is a plasma protein that binds sialoglycoproteins in podocytes, leading to proteinuria, foot process effacement, and cytoskeletal rearrangement [81, 82]. Another mediator upregulated in MCD and FSGS, C-maf inducing protein (c-mip), leads to proteinuria without inflammatory lesions or cell infiltration in transgenic animals [83]. Changes in the podocyte expression of angiopoietin-like 4 induce proteinuria, foot process effacement, and dyslipidemia [84]. These studies need confirmation in animal and clinical models.

Clinical Features

Nephrotic syndrome may begin during infancy, but usually occurs between the ages of 2 and 7 years. Nephrotic range proteinuria is rarely discovered during routine urinalysis. The onset of illness is often preceded by an upper respiratory tract infection, followed by edema, which becomes clinically detectable when fluid retention exceeds 3–5% of body weight [1]. Periorbital edema, frequently misdiagnosed as allergy or as conjunctivitis, is often the initial symptom. As edema is gravity dependent, periorbital puffiness decreases during the day, while it localizes at the lower extremities. In the reclining position, it localizes on the dorsal part of the body. Edema of the scrotum, penis, or labia may be seen. Edema is soft and pitting, and easily elicited. Anasarca may develop with ascites, and pleural and pericardial effusions. Rapid formation of ascites is often associated with abdominal distension, pain, and malaise; dyspnea is rare. However, these symptoms may also be related to a complication such as peritonitis, thrombosis, or rarely, pancreatitis. Cardiovascular shock is not unusual, secondary to the sudden fall of plasma albumin, with abdominal pain and symptoms of peripheral circulatory failure with cold extremities and hypotension. Blood pressure is usually normal, but sometimes elevated.

Macroscopic hematuria is rare, observed in 1% of cases. The disease may also be revealed by a complication. Peritonitis due to *Streptococcus pneumoniae* might be the presenting feature at onset of the illness [1], although this has decreased in prevalence due to immunizations. Deep vein or arterial thromboses and pulmonary embolism may also occur during the first episode or during a relapse.

Evaluation

Urinalysis

Nephrotic range proteinuria is defined as urine protein excretion >50 mg/kg/day or 40 mg/h/m^2. The morning “spot” urine protein/creatinine ratio above 2 mg/mg (200 mg/mmol) is the most commonly reported cut off value for nephrotic range proteinuria and corresponds to a dipstick value +3 or above (Table 1). In most cases, proteinuria is highly selective, consisting of albumin and low

Table 1 Investigations in patients with steroid-sensitive nephrotic syndrome

Essential at onset
Urinalysis[a]
Complete blood counts
Blood levels of urea, creatinine, electrolytes, total protein, albumin; lipid profile
Tuberculin test
Additional evaluation, if required, at onset or relapse
Tuberculin test: Areas with transmission of tuberculosis Chest radiography: Positive tuberculin test or history of contact with tuberculosis; suspected lower respiratory tract infection
Renal ultrasonography: Planned for kidney biopsy; presence of gross hematuria; suspected renal vein thrombosis
Complete blood counts: Suspected systemic infection or hypovolemia
Blood urea, creatinine, albumin, electrolytes: Severe edema; hypovolemia/dehydration; oliguria/anuria; prolonged (>72 h) diuretic therapy
Complement C3, C4, antinuclear antibody, antistreptolysin O: Gross, persistent microscopic hematuria; sustained hypertension; suspected secondary cause (systemic lupus, IgA vasculitis, C3 glomerulopathy)
Serum transaminases; hepatitis B surface antigen; antibody against hepatitis C virus: History of jaundice or liver disease
Periodic monitoring, if relapsing illness
Blood creatinine; albumin, electrolytes

[a] Quantitative estimation of urine protein is required if nephrotic range proteinuria is uncertain

molecular weight proteins. Selectivity of proteinuria, estimated by the Cameron index, is the ratio of clearance of IgG (molecular weight 150 kDa) to transferrin (80 kDa). The index in selective proteinuria is below 0.10. Nonselective proteinuria (value >0.20) is often associated with SRNS and FSGS. However, there is a considerable overlap in results, and the test has limited value. The amount of protein excreted in the urine does not reflect the quantity of protein crossing the glomerular basement membrane, since a significant amount is reabsorbed in the proximal tubule.

Urine microscopy shows fat bodies. Hyaline casts are found in patients with nephrotic range proteinuria while granular casts may be associated with acute kidney injury. Microscopic hematuria is present in 20% of cases and has limited histopathologic or prognostic significance. Urine sodium excretion is low and associated with sodium retention and edema.

Biochemistry

The total serum protein level is markedly reduced. Characteristically, albumin concentration usually falls below 2 g/dL and is often less than 1 g/dL. Reporting serum albumin concentration depends on the methodology. The values obtained by bromocresol green colorimetry are ~5.5 g/l higher than those measured by bromocresol purple (colorimetric), capillary electrophoresis, or immunonephelometry. Serum electrophoresis shows low levels of albumin and γ-globulins, and increased α-2 and β-globulins. Blood levels of IgG are markedly decreased, IgA is slightly reduced, IgM is increased, and IgE is normal or increased. Among other proteins, fibrinogen and β-lipoproteins are increased; small molecules such as antithrombin III are lost in the urine and their concentration in plasma is decreased.

Hyperlipidemia in nephrotic syndrome results from: (i) increased hepatic synthesis of cholesterol, triglycerides, and lipoproteins in response to decreased intravascular oncotic pressure; (ii) decreased catabolism of lipoproteins due to reduced activity of lipoprotein lipase that transforms VLDL to LDL via IDL; and (iii) reduced activity of LDL receptor and increased urinary loss of HDL [85, 86]. Increased plasma concentrations of proprotein convertase subtilisin/kexin type 9 (PCSK9), which reduces hepatic uptake of LDL by downregulation of the LDL receptor, have been reported in patients with nephrotic syndrome, and might contribute to hyperlipidemia [87]. Total and LDL cholesterol are elevated, while HDL cholesterol remains unchanged or low, particularly HDL2, leading to increased ratio of LDL/HDL cholesterol [88]. Patients with severe hypoalbuminemia have increased triglycerides and VLDL. Apoproteins, apo B, apo CII, and apo CIII are increased. Levels of lipoprotein Lp(a) are elevated, contributing to cardiovascular and thrombotic complications.

These abnormalities are transient and resolve following remission.

Serum electrolytes are usually within the normal range. A low sodium level may reflect renal retention of water due to hypovolemia and the syndrome of inappropriate antidiuresis. Mild reduction of plasma sodium concentration might be due to reduced fraction of plasma water, as seen in patients with severe hyperlipidemia or paraproteinemia (pseudohyponatremia). Although serum total calcium is low as a result of hypoalbuminemia, levels of ionized calcium are normal. Serum creatinine is usually within the normal range but may be high due to intravascular volume depletion or acute kidney injury [89].

Hematology

Hemoglobin levels and hematocrit are increased in patients with plasma volume contraction. Thrombocytosis is common and may reach 5×10^8 or 10^9/l.

Renal Biopsy

A kidney biopsy is not required in a child aged 1–14 years with typical features of nephrotic syndrome, who shows complete remission of proteinuria following therapy with corticosteroids. The indications for biopsy include steroid resistance, defined as the lack of complete remission despite 6-weeks daily therapy with prednisone, macroscopic or persistent microscopic hematuria, persistently elevated creatinine levels or sustained hypertension, extrarenal signs or symptoms suggesting a systemic disease, or low C3 level suggesting glomerular disease, other than minimal change nephrotic syndrome.

Nephrotic syndrome presenting in infancy is often secondary to a genetic cause and appropriate testing is indicated. If genetic analysis is not available, experts suggest performing a kidney biopsy before initiating therapy with corticosteroids. Biopsy is not indicated in SSNS before starting treatment with a corticosteroid-sparing agent as the histopathologic features (MCD, diffuse mesangial proliferation, FSGS, or IgM nephropathy) have no impact on the choice of therapy in patients who continue to be steroid sensitive. However, a kidney biopsy may be performed in patients receiving calcineurin inhibitors for assessment of nephrotoxicity.

Light microscopy shows three morphological patterns. The most common is MCD, followed by diffuse mesangial proliferation and FSGS found in 5–7% of biopsies, each [90, 91].

Minimal Change Disease (MCD)

On light microscopy, the glomeruli show normal capillary walls and normal cellularity (Fig. 1). Swelling and vacuolation of epithelial cells (podocytes) and slight increase in mesangial matrix are often observed. Mild mesangial hypercellularity and scattered foci of tubulointerstitial lesions and [5]. Vascular changes are absent. Ultrastructural changes are always present, involving podocytes and the mesangial stalks. Podocyte foot process fusion is generalized and constant (Fig. 2). There is no direct correlation between the degree of ultrastructural injury and severity of proteinuria [92]. Other epithelial changes consist of microvillus formation and the presence of numerous protein reabsorption droplets. The glomerular basement membranes are normal with no deposits; endothelial cells are often swollen. Mesangial

alterations include mild mesangial cell hypercellularity, increased matrix, and finely granular osmiophilic deposits along the internal aspect of the basement membrane. Ultrastructural alterations are nonspecific and reverse following remission of proteinuria.

Immunofluorescence examination is negative in most cases; in some, there may be weak mesangial deposition of C3 that lacks correlation with clinical presentation or outcomes.

Diffuse Mesangial Proliferation

The biopsy shows a marked increase in mesangial matrix associated with hypercellularity, although these features are often observed in those with SRNS (Figs. 3 and 4) [5, 6, 93]. Peripheral capillary walls are normal. Electron microscopy shows foot process fusion, similar to the changes observed in MCD. The presence of mesangial hypercellularity has been found to have prognostic significance with a higher rate of progressive kidney disease in some studies [93].

Focal Segmental Glomerulosclerosis (FSGS)

Although FSGS is frequently observed in patients with SRNS, it may be observed in up to 10% of children with SSNS. FSGS affects a variable proportion of glomeruli [5, 94]. These lesions initially affect glomeruli in the juxtamedullary cortex. In order to reduce the risk of missing focal lesions, adequate sampling is necessary. It has been suggested that the risk of missing a lesion is 35% when the sample contains 10 glomeruli, and 12% if the sample contains 20 glomeruli [95].

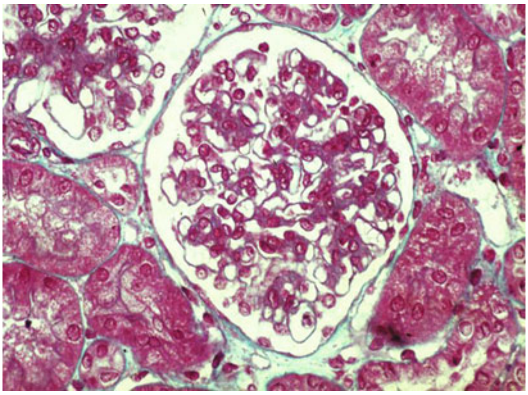

Fig. 3 Diffuse mesangial proliferation : increased number of mesangial cells and thickening of the mesangial matrix. Trichrome light green, X200. (Courtesy of MC Gubler, MD)

The focal changes are limited to a part of the tuft; other capillary loops show no modification. The lesions predominate in the deeper cortex at the corticomedullary junction [96]. Segmental lesions affect a few capillary loops, which stick together either at the hilum or at the periphery of

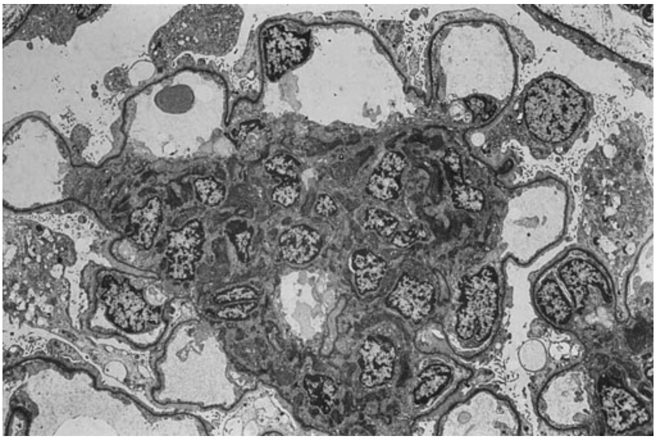

Fig. 4 Diffuse mesangial proliferation with marked increased in the number of mesangial cells, associated with diffuse effacement of podocyte foot processes. Electron microscopy. Silver methenamine ×2500. (Courtesy of MC Gubler, MD)

the tuft or at both [97, 98]. The clinical course is reported to be benign when the location of these sclerotic lesions is peripheral (tip lesions), although such findings have not been confirmed by others [96, 99]. Hyaline material is often present within the sclerotic lesions. A clear "halo" is observed at the periphery of the sclerotic segments (Fig. 5). The segmental lesion has a different aspect depending on whether it affects a group of capillary loops free in Bowman space or is adherent to Bowman capsule. The "free" sclerotic segments are always surrounded by a "crown" of flat or hypertrophied podocytes. The podocytes form a continuous layer overlying the damaged areas of the tuft and in close apposition to the clear "halo." When the sclerotic lesion is adherent to Bowman capsule, there is a direct synechiae between the collapsed capillary loops and Bowman basement membrane. The rest of the tuft and the non-sclerotic glomeruli show "minimal changes" with foot process fusion. Glomerular hypertrophy is common in FSGS, and when such hypertrophy is found in MCD, it might be predictive of progression to FSGS [100]. Tubular atrophy and interstitial fibrosis are often present and proportional to the glomerular damage [6, 101]. Focal glomerular lesions should therefore be suspected when focal tubular and interstitial changes are found associated with minimal glomerular changes.

On electron microscopy, the FSGS lesion is characterized by the presence of paramesangial and subendothelial, finely granular, osmiophilic deposits [101] with either disappearance or swelling of endothelial cells and an increase in mesangial matrix material. Fatty vacuoles may be seen, either in the middle of the abnormal deposit or in the cytoplasm of endothelial and mesangial cells. The peripheral synechiae, between podocytes and basement membrane, is formed by the apposition of acellular material in which thin and irregular layers of newly formed basement membranes are visible (Fig 6). Modifications of the podocytes consist of focal cytoplasmic degeneration, breakdown of cell membranes, and detachment of epithelial cells from basement membranes, with filling of the resulting space by cell debris and new membranes [102].

A pathologic classification of FSGS, designated the Columbia classification, is proposed with five histological variants [103]:

i. FSGS not otherwise specified (NOS) or classic FSGS, the most frequent variant.
ii. The perihilar variant with lesions located at the vascular pole of the glomerular tuft.
iii. The cellular variant with podocyte hyperplasia and endocapillary hypercellularity, foam cells, and leukocyte infiltration.
iv. The tip variant, where the lesion involves the tubular pole, is the most benign form of FSGS with presenting features and outcome more close to MCD [104].
v. Collapsing variant or collapsing glomerulopathy characterized by segmental or global wrinkling and collapse of the glomerular capillary walls with prominent hypertrophy and hyperplasia of the overlying podocytes.

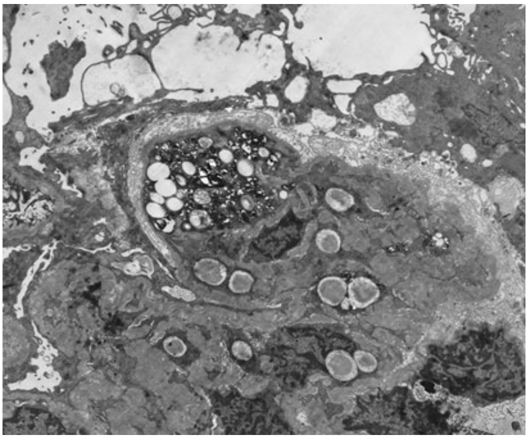

Fig. 6 Focal and segmental hyalinosis. The capillary loop is obliterated by increase in mesangial material mixed with granular deposits and lipid droplets. The lesion sis surrounded by thin layers of newly formed membranes. Podocytes are vacuolated and show diffuse loss of foot processes. Electron microscopy. Uranyl acetate and lead citrate, ×3500. (Courtesy of MC Gubler, MD)

This classification has clinical implications in terms of response to therapy and risk of progression to renal failure. For example, glomerular tip lesions have been associated with better outcomes and collapsing variant with worse outcomes [99]. The former lesion was predictive of favorable response to therapy in a pediatric series [105]. Patients with collapsing glomerulopathy have severe nephrotic syndrome, unsatisfactory response to corticosteroids, and rapidly progress to renal failure.

Immunofluorescence Patterns

IgM-Associated Nephropathy

Occasionally, patients with MCD have biopsies that show mesangial deposits of IgM, IgG, C3, and rarely IgA on immunofluorescence microscopy. Mesangial deposits of IgM are the most common (Fig. 7). Habib et al. reported on 54 children with INS and glomerular IgM deposits in the glomeruli. There was no correlation between IgM deposits and the initial response to corticosteroids or the final outcome [106]. The impact of mesangial IgM deposits on the clinical course is unclear. Some experts suggest that IgM nephropathy is a distinct entity associated with hypertension, CKD, and steroid dependence or resistance [107]. Others show that mesangial IgM deposits do not correlate with outcomes in patients with nephrotic syndrome [108].

C1q Nephropathy

This entity, first described by Jennette and Hipp in 1985, presents with mesangial deposition of immunoglobulins and complement components, predominantly C1q, and mesangial electron-dense deposits [109, 110]. Clinical features vary from asymptomatic proteinuria or hematuria to

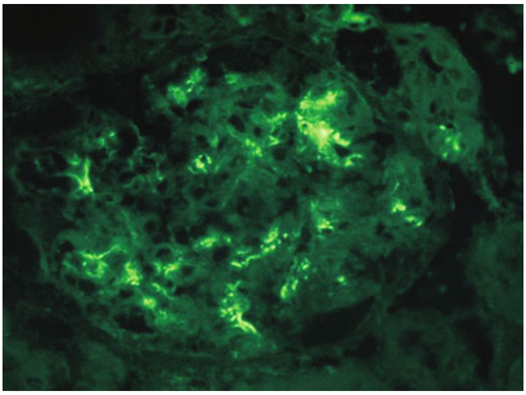

Fig. 7 Presence of mesangial IgM deposits. (Immunofluorescence ×280) (Courtesy of MC Gubler, MD)

nephrotic or nephritic syndrome, and no clinical or serologic evidence of systemic lupus erythematosus. C1q deposits may be found in association with MCD or FSGS [111]. The disappearance of C1q deposits or development of FSGS has been reported on follow-up biopsies [112]. C1q deposits in patients with MCD may be associated with frequent relapses and shorter relapse-free periods, corticosteroid dependence, and need for second-line therapy, but without impact on progression or long-term outcomes [113, 114].

IgA Deposits and MCD

Patients with SSNS may occasionally show mesangial deposits of IgA. While some experts consider the histology as being compatible with IgA nephropathy, others propose that the presence of mesangial IgA in patients with minimal change disease, i.e., without mesangial proliferation is coincidental [108, 115, 116]. These patients show rapid response to therapy with prednisolone, which is not seen in IgA nephropathy.

Therapy

Management of Initial Episode

Following the diagnosis of nephrotic syndrome, specific therapy is initiated with oral corticosteroids (prednisone or prednisolone; hereafter referred to as prednisone). In 1981, the ISKDC empirically proposed that the first episode of nephrotic syndrome be treated with daily prednisone for 4 weeks, followed by intermittent therapy (3 consecutive days in a week) for next 4 weeks, and then discontinued [7]. Later, a randomized controlled trial (RCT) showed that therapy with prednisone for 6 weeks daily, followed by alternate day for next 6 weeks was better in terms of reduced incidence of relapses over the next 12–24 months [117]. In efforts to define optimal therapy for the initial episode, several RCTs investigated the duration and dose of prednisone, based on which a 2007 meta-analysis concluded that therapy for 6 months was associated with reduced risk of relapses and lower risk of frequent relapses (relative risk, RR 0.55; 95% CI 0.39–0.80) [118]. However, most studies included in the meta-analysis had methodological flaws, resulting in high risk of bias.

Four multicenter RCTs published in the last 7 years have challenged the previous results. These studies, representing outcomes in over 800 patients across the Netherlands, the UK, Japan, and India, show that extending initial therapy beyond 8–12 weeks does not influence the time to first relapse or the risk of frequent relapses at 1–2 years' follow-up. All these studies had low risk of bias; three were placebo-controlled. A meta-analysis that included these studies showed that the risk of frequent relapses at 1–2 years follow-up was not different for 3 months or longer versus 2 months therapy (RR 0.86; 95% CI 0.65–1.13), and for 5 months or longer versus 3 months therapy (RR 0.70; 95% CI 0.45–1.08) [119–121]. Subgroup analysis, limited to studies at low risk of bias, indicated identical risk for frequent relapses in patients treated for 2–3 months versus 3–6 months. *Post-hoc* analyses of two studies suggest a trend for benefit with prolonged therapy in young children; this finding requires confirmation [120, 121].

Based on the above, experts recommend that therapy for the initial episode comprise of prednisone at a dose of 60 mg/m^2/day (2 mg/kg/day, maximum 60 mg in 1–2 divided doses) for 4–6 weeks, followed by 40 mg/m^2 (1.5 mg/kg, maximum 40 mg as single morning dose) on alternate days for the next 4–6 weeks, and then discontinued [120, 121].

Based on pharmacokinetics and variations by age, prednisone is usually dosed by body surface area in children [122]. However, estimation of body surface area involves complex formulae with variable results [123]. Calculation using body weight is more convenient but results in relative underdosing, particularly in young children [123, 124]. Underdosing, using weight-based calculations, may be associated with increased risk of relapses in some [125, 126], but not all studies [127, 128]. For young children, experts therefore prefer to administer prednisone based on body surface area [122].

Daily prednisone is administered in single or divided doses, with similar time to remission [120, 129]. Most evidence on corticosteroid therapy is limited to the use of prednisone or its biologically active metabolite, prednisolone [130]. The use of deflazacort, based on one RCT and few case series, continues to be limited [131]. Prednisone is best given following food; therapy with antacids, ranitidine, or proton pump inhibitors is not routinely required [120].

Disease Course and Therapy of Relapses

While the disease course varies in patients with SSNS, more than 75% patients show one or more relapses on follow-up [9, 132] (Table 2). Almost one-half of the relapses are precipitated by minor infections, usually of the upper respiratory tract. A relapse has conventionally, albeit empirically, been treated with prednisone at 60 mg/m^2/day (2 mg/kg/day; maximum 60 mg) in single or divided doses until remission (protein trace/nil for 3 consecutive days), followed by 40 mg/m^2 (1.5 mg/kg, maximum 40 mg) on alternate days for 4 weeks [120, 121]. Remission is achieved by 7–10 days and daily therapy is seldom necessary beyond 2 weeks. In case of persistent proteinuria, daily therapy with prednisone may be extended, to maximum of 6 weeks. Lack of remission despite treatment with 6-weeks' daily prednisone indicates late (secondary) steroid resistance that requires specific evaluation and management [121].

Retrospective studies and small RCTs suggest that reduced dose [133] or abbreviated duration of therapy [134] with prednisone is effective in

Table 2 Definitions of disease course in nephrotic syndrome

Nephrotic range proteinuria	Urine dipstick protein 3+ (300 mg/dL)[a] or more; first-morning spot urine protein to creatinine ratio (UPCR) >2 mg/mg; 24-h protein >1000 mg/m^2
Remission	Dipstick protein nil or trace (<30 mg/dL) for 3 consecutive days; UPCR <0.2 mg/mg (<0.5 mg/mg in children younger than 2-year-old); urine protein <4 mg/m^2/h
Relapse	Urine dipstick protein ≥3+ (300 mg/dL) for 3 consecutive days; UPCR >2 mg/mg, or urine protein >40 mg/m^2/h
Steroid-sensitive nephrotic syndrome	Remission within 6 weeks of therapy with prednisone at standard dose (60 mg/m^2/day or 2 mg/kg/day; maximum 60 mg/day)
Steroid-resistant nephrotic syndrome	Lack of remission despite therapy with daily prednisone at a dose of 2 mg/kg (or 60 mg/m^2) daily for 6 weeks
Frequently relapsing nephrotic syndrome	Two or more relapses in the first 6 months after stopping initial therapy, or ≥3 relapses in 1 year
Steroid-dependent nephrotic syndrome	Two consecutive relapses when on alternate day steroids or within 14 days of cessation of therapy
Significant corticosteroid toxicity	Hyperglycemia (fasting glucose >100 mg/dL, postprandial >140 mg/dL, HbA1c >5.7%); obesity (BMI > 27 kg/m^2); short stature (height < ¯2 SDS) with height velocity (<¯3 SDS for age); glaucoma; cataract(s); myopathy; osteonecrosis; or psychosis

[a] False positive if urine pH >7.0; false negative if specific gravity ≤1010

inducing and maintaining remission. Well-powered studies are required to confirm these findings and evaluate the optimal dose and duration of prednisone for treatment of relapses.

Management of Frequent Relapses

The disease course varies in patients with SSNS; 35–40% have a single episode or infrequent relapses, and 50–55% show frequent relapses (FRNS) or steroid dependence (SDNS) [9, 132] (Table 2). Risk factors for frequent relapses and steroid dependence include an early age at onset (≤3-year), delayed time to remission, and inadequate initial steroid therapy. Patients with a fast relapse (duration of initial remission less than 6 months) are also at risk for subsequent frequent relapses [9, 132, 135, 136]. Relapses may be associated with significant complications, including life-threatening infections, hypovolemia, and thrombosis. Therapy with multiple courses of high-dose prednisone is associated with significant toxicity, including obesity, cushingoid features, behavioral problems, cataract, glaucoma, glucose intolerance, hypertension, osteoporosis, and avascular hip necrosis.

Choice of Therapy

Patients with frequent relapses or steroid dependence are initially treated with long-term alternate day steroids. Those continuing to show frequent relapses or features of steroid toxicity are offered therapy with steroid-sparing agents. Since few prospective studies have compared the relative efficacy and safety of steroid-sparing agents, most guidelines do not specify the precise order or specific choice of alternative therapy [120, 121] (Table 3). The choice of steroid-sparing therapy for these patients is therefore based on considerations of its efficacy and adverse effects, patient age, steroid threshold, severity of relapses, and features of steroid toxicity. Potent medications are preferred in patients with high steroid threshold (>1 mg/kg on alternate days) relapses, relapses associated with life-threatening complications, or if associated with significant steroid toxicity (Table 2). Figure 8 summarizes a proposed schema for the management of these patients. Patients who relapse despite therapy with two or more steroid-sparing agents (difficult-to-treat steroid-sensitive disease) are considered for therapy with calcineurin inhibitors, and failing that rituximab. While the approach to management indicated in Fig. 8 suffices in most instances, individual situations may require different preference. Therapy with oral cyclophosphamide is avoided in young patients, and in pubertal or postpubertal boys. Therapy with calcineurin inhibitors may be preferred to mycophenolate mofetil (MMF) in very young patients with significant steroid toxicity. The use of rituximab is avoided in young children due to the risk of hypogammaglobulinemia.

The above interventions aim to reduce the frequency of relapses, and wherever possible, stoppage of corticosteroid therapy. Occurrence of sustained remission or up to one relapse in 6 months is considered acceptable, and except in severe steroid dependence, therapy with corticosteroids may be tapered and discontinued over few months.

Long-Term Alternate Day Steroids

The dose of prednisone is tapered to the lowest dose required to maintain the patient in remission without significant adverse effects. A dose of 0.5–0.7 mg/kg given on alternate days for 6–12 months is effective in reducing relapses or maintaining remission in 30–40% patients [120]. While this regimen is commonly used as first line to reduce the risk of relapses, there are no randomized trials to support its use.

Since relapses are precipitated by minor infections, three RCTs have examined the role of short-term (5–7 days) daily administration of steroids in reducing infection-related relapses [137–139]. Although all studies showed reduced relapse rates with the intervention, one had a small sample size

Table 3 Immunosuppressive medications for frequent relapses

Medication	Dose	Duration	Adverse effects	Recommended monitoring
Prednisone	0.5–0.7 mg/kg on alternate days[a,b] Reduce dose if sustained remission	6–12 months	Cushingoid features; short stature; hypertension; raised intraocular pressure; glucose intolerance; cataract; elevated transaminases	Screen for side effects, hypertension Anthropometry q 3–6 months; eye evaluation q 6–12 months; glucose and transaminases q 3–6 months
Levamisole	2–2.5 mg/kg on alternate days	2–3 years	Leukopenia, ANCA positive vasculitic rash, high transaminases, seizures	Blood counts q 2–3 months; transaminases q 4–6 months
Cyclophosphamide	2–2.5 mg/kg/day orally	8–12 weeks	Leukopenia, alopecia, infections; discolored nails; hemorrhagic cystitis; risk of gonadal toxicity and malignancies	Blood counts q 2 weeks Maintain hydration; discontinue during infections Co-administer with prednisone 1 mg/kg AD; taper and discontinue prednisone after 4–8 weeks
Mycophenolate mofetil	600–1200 mg/m^2/day in divided doses; AUC >45 mg·h/L	2–3 years	Abdominal pain, diarrhea, nausea, weight loss; viral warts; leukopenia; elevated transaminases	Screen for adverse effects Blood counts and transaminases q 3–6 months
Cyclosporine	4–5 mg/kg/day in divided doses; trough 50–100 ng/mL[a]	2–3 years	*Both:* Nephrotoxicity, hyperkalemia, hepatotoxicity *Cyclosporine:* Gingival hyperplasia, hypertrichosis; hypertension; dyslipidemia *Tacrolimus*: Tremors, seizures, headache; diarrhea; glucose intolerance; hypomagnesemia	Screen for cosmetic side effects, tremors, diarrhea, hypertension Creatinine, potassium at 2–4 weeks, q 3–6 months Liver function tests, glucose, uric acid, magnesium and lipids q 3–6 months
Tacrolimus	0.1–0.2 mg/kg/day in divided doses; trough 4–8 ng/mL[a]	2–3 years		
Rituximab	375 mg/m^2 as slow IV infusion	Two doses one week apart[c]	Chills, fever; serum sickness; bronchospasm; acute lung injury Neutropenia; *P. jirovecii* pneumonia; reactivation of hepatitis B or JC virus; hypogammaglobulinemia	*Pre-dose*: Blood counts, transaminases; hepatitis B and HIV serology; immunoglobulin G (IgG) level *Post-therapy:* Monitor CD19 and blood counts; IgG level; consider cotrimoxazole prophylaxis

[a] May reduce dose further if remission is sustained

[b] During infections, administer alternate day prednisolone at 0.5 mg/kg every day for 5–7 days to prevent relapse

[c] One to two additional doses are given at weekly intervals if CD19+ cells are >5/μL (or > 1% of CD45+ cells) despite two doses of rituximab (Modified from Indian Pediatrics 2021)

[137], and another did not examine long-term benefits [138]. A prospective large RCT showed that daily administration of small dose of prednisone during infections independently reduced annual relapse rates by 59% (rate ratio, 0.41; 95% CI 0.3, 0.6) without the risk of steroid toxicity. Six patients needed to be treated to prevent the occurrence of frequent relapses in one [139]. Based on the above findings, expert guidelines suggest that the frequency of administration of prednisone be increased from alternate day to daily during episodes of fever or upper respiratory tract infection

Fig. 8 Management of frequently relapsing or steroid dependent nephrotic syndrome. The initial strategy is to administer prednisone at a dose of 0.5–0.7 mg/kg on alternate days for 6–12 months. Daily therapy at the same dose for 5–7 days, during minor infections, prevents infection-associated relapses. Patients who relapse at prednisone threshold >0.7 mg/kg or show steroid toxicity require therapy with steroid-sparing medications (Table 3). Levamisole or mycophenolate mofetil (MMF) are preferred agents for mild disease. Patients with high steroid threshold (>1 mg/kg on alternate days) or with significant steroid toxicity (Table 2) may be treated with MMF at higher doses (1000–1200 mg/m^2/day) or cyclophosphamide. The use of cyclophosphamide is avoided in children <5–7 year-old and in peripubertal boys due to reduced efficacy and risk of gonadal toxicity, respectively. Patients who relapse despite therapy with two or more steroid-sparing agents are considered for therapy with calcineurin inhibitors (CNI; cyclosporine or tacrolimus) and rituximab. (Modified from Indian Pediatrics 2021)

[120, 121]. A trial comprising 365 patients (PREDNOS 2; ISRCTN10900733) failed to show benefit of 6-days low dose prednisone in reducing the risk of infection-associated relapses.

More than four decades ago, Leisti et al. proposed that suppression of the hypothalamo-pituitary-adrenal axis was in itself a risk factor for relapses, and administration of low-dose daily prednisone was effective in preventing repeated episodes of nephrotic syndrome [140]. Data from a case series [141] and an open-label RCT [142] suggests that low dose (0.2–0.3 mg/kg) daily prednisone is associated with fewer relapses than twice the dose (0.5–0.7 mg/kg) on alternate days. The strategy led to lower steroid requirement and was not associated with toxicity [142]. These findings require confirmation in studies with longer follow-up that are powered to examine adverse effects, including suppression of the hypothalamo-pituitary-adrenal axis.

Children with FRNS (or SDNS) may be treated with steroid-sparing agents when low-dose alternative-day prednisone therapy fails and/or severe adverse steroid-related events develop. A recent Cochrane systematic review of RCT indicated that cyclophosphamide, levamisole, calcineurin inhibitors, mycophenolate mofetil (MMF), and rituximab substantially reduce the incidence of relapse in children with FRNS or SDNS [143]. There are limited studies that compare the efficacy of steroid-sparing medications. The choice of the agent is chiefly based on drug efficacy, adverse effects, patient condition, and physician preference. A suggested schema for management is shown in Fig. 8. Larger studies are needed to determine how these medications should be used in patients.

Cyclophosphamide

Cyclophosphamide, the most commonly used steroid-sparing agent, has been documented in RCTs to effectively treat FRNS [144, 145]. The Cochrane review reported that cyclophosphamide significantly reduced relapse risk at 6–12 months compared to prednisone alone (4 studies, 161 children; risk ratio (RR) 0.47, 95% CI 0.34–0.66) [143]. Several reports demonstrate that cyclophosphamide is not sufficiently effective for SDNS [146–149]. A systematic review reported that remission rates in children with FRNS were 72% after 2 years and 36% after 5 years; rates in patients with SDNS were 40% and 24%, respectively [150]. Major side effects of this agent include gonadal dysfunction (azoospermia), leukopenia, infection, alopecia, hemorrhagic cystitis, and hepatic dysfunction. The risk of azoospermia is higher in boys of pubertal age (Tanner stage 2 or greater) or postpubertal age, when cumulative dose of cyclophosphamide exceeds 100–300 mg/kg, although higher doses may be safe in prepubertal boys [150, 151]. Usually, significantly lower doses of cyclophosphamide are prescribed typically 2–2.5 mg/kg for 8–12 weeks (total dose 180–200 mg/kg), with a maximum daily dose of 100 mg and only as a single course [120, 121, 152]. The risk of female infertility is considered to be lower and a cumulative dose ~200 mg/kg is reported safe, as infertility occurred at a dose of 300 mg/kg or higher [150, 151]. Approximately 32% of patients with nephrotic syndrome develop leukopenia, during cyclophosphamide therapy. The dose of cyclophosphamide is reduced if the leukocyte count drops below 4500/mm^3; therapy is suspended when the count falls below 3000/mm^3 [150].

Levamisole

Levamisole has immunomodulatory properties and a favorable side effect profile. More than 25 years ago, it was reported that levamisole reduced the risk of relapse compared with placebo [153]. However, levamisole was withdrawn from the market in 1999 in the United States because of adverse effects, mainly agranulocytosis and antineutrophil cytoplasmic antibody (ANCA)-positive vasculitis, and in Europe in 2004 because of a lack of clear indications [154]. Nevertheless, in many centers, levamisole has been used as the first-line steroid-sparing treatment of FRNS or SDNS for decades [120]. Recently, an international, multicenter, double-blind, placebo-controlled randomized trial was conducted to examine the efficacy and safety of levamisole in children with FRNS and SDNS. Between 100 days and 12 months after start of study drugs, the time to relapse (primary endpoint) was significantly increased in patients treated with levamisole compared to placebo [hazard ratio (HR) 0.22, 95% CI 0.11–0.43]. Six percent of placebo versus 26% of patients receiving levamisole were in remission at 12 months. The most frequent serious adverse event was asymptomatic neutropenia, which was reversible spontaneously or after treatment discontinuation. Thus, levamisole prolonged the time to relapse and prevented recurrence during 1-year therapy compared with placebo [155]. According to the Cochrane review, levamisole was as effective as MMF in ensuring sustained remission at 12-months (1 study, 149 children, RR 0.90, 95% CI 0.70–1.16) [143]. Similarly, levamisole was as effective as cyclophosphamide in the proportion of children relapsing at 6–9 months (2 studies, 97 children, RR 1.17, 95% CI 0.76–1.81), at 12 months (1 study, 40 children, RR 0.89, 95% CI 0.68–1.16), and at 24 months (1 study, 40 children, RR 0.89, 95% CI 0.73–1.10). Adverse effects (infection, leukopenia) may not differ between these treatment groups [143].

Cyclosporine

Cyclosporine is effective for FRNS or SDNS, although most patients experience relapses after discontinuing the drug (cyclosporine dependence) [156–163]. Blood concentration of cyclosporine should be monitored, usually by 12-h trough or C2 (2-h post-dose) levels. In a Japanese multicenter prospective RCT of cyclosporine in 44 children with FRNS, higher 2-year relapse-free rate was shown in the dose-adjustment group (12-h trough 80–100 ng/mL for 6 months, and 60–80 ng/mL for 18 months) than in the fixed-dose group (2.5 mg/kg/day for 24 months) (50% vs. 15%, $P = 0.006$) [156]. Thereafter, a multicenter study using a microemulsified preparation of cyclosporine (Neoral®) in 62 patients, conducted with dose adjustments based on the above trough levels, showed that the medication was effective and safe (2-year relapse-free rate 58%; nephrotoxicity 8.6%) [157]. Another study demonstrated that long-term cyclosporine therapy (more than 2 years; median 34 months) with trough level of 50–100 ng/ml is effective and safe [159]. The area under the time-concentration curve ($AUC_{0–4}$) of cyclosporine most strongly correlates with C2 in patients with nephrotic syndrome and in kidney transplant recipients. With this background, a multicenter RCT was conducted in Japan in 93 children with FRNS to compare two different target C2 levels: a higher C2 group (target 600–700 ng/mL for the first 6 months, followed by 450–550 ng/mL for the next 18 months) and a lower C2 group (target 450–550 ng/mL for the first 6 months, followed by 300–400 ng/mL for the next 18 months). There was no difference in the proportion of patients who were relapse-free at 24 months. However, patients in the high C2 group had fewer relapses and were likely to show infrequent relapses during the study period [164]. Results from these studies show that the dose of cyclosporine should be adjusted within target levels (trough 50–100 ng/ml; C2 300–700 ng/ml).

Chronic nephrotoxicity is the most problematic side effect of cyclosporine; its risk is increased after prolonged use (2 years or more) [165, 166]. Since it is not possible to diagnose cyclosporine-induced chronic nephrotoxicity by urinalysis and blood tests, a kidney biopsy might need to be performed in case of long-term administration; prolonged therapy is avoided [167]. Treatment with cyclosporine may result in cosmetic side effects (hypertrichosis, gingival hypertrophy), infections, hypertension, and the posterior reversible encephalopathy syndrome [156–163, 168].

Tacrolimus

Although there are no RCTs, several case series suggest that tacrolimus is effective in patients with FRNS or SDNS [169–171]. In a nonrandomized prospective study on 72 patients, tacrolimus and MMF were found to be similarly effective in maintaining remission [172]. A retrospective study also suggested that tacrolimus was more effective than MMF in prevention of relapses, but resulted in adverse events such as infections and pancreatitis [173]. Tacrolimus may therefore be considered for treating FRNS or SDNS when cyclosporine cannot be used because of cosmetic side effects (hypertrichosis, gingival hypertrophy).

A multicenter, open-label RCT to examine whether tacrolimus is non-inferior to cyclosporine in patients with FRNS or SDNS (JSKDC06; UMIN000004204) is in progress. Potential onset of diabetes mellitus and chronic nephrotoxicity are important side effects of tacrolimus; the latter often correlates with high trough levels of the agent [169]. Based on experience with kidney transplantation, trough levels in most previous studies were adjusted to 5–10 ng/mL.

Mycophenolate Mofetil (MMF)

MMF, a purine metabolism antagonist, has been used as a steroid-sparing agent for FRNS or SDNS because of its favorable side effect profile and lack of nephrotoxicity. RCTs suggest that MMF was well tolerated and beneficial in patients with FRNS or SDNS, but less effective than cyclosporine or tacrolimus [174–176]. MMF is recommended as steroid-sparing therapy in the Children's Nephrotic Syndrome Consensus

Conference [177], KDIGO [121], and the Indian Society of Pediatric Nephrology [120] guidelines, for patients with FRNS or SDNS. According to the Cochrane review, though with low certainty evidence, MMF has little or no difference compared to cyclosporine in the proportion of patients who relapse within 12 months (2 studies, 82 patients; RR 1.90, 95% CI 0.66–5.46) and relapse rate per year (3 studies, 142 patients; mean difference 0.83, 95% CI 0.33–1.33) [143]. Therapy with MMF, compared with cyclosporine, decreases the proportion of patients with hypertrichosis (3 studies, 140 patients; RR 0.23, 95% CI 0.10–0.50) and gingival hypertrophy (3 studies, 144 patients; RR 0.09, 95% CI 0.02–0.47); there were no differences in the proportion of patients with other adverse effects (hypertension, lymphopenia, decreased GFR, pneumonia, and diarrhea).

Therapy with MMF is an important step in the management of patients with FRNS or SDNS. Patients who respond to therapy with reduction in frequency of relapses may receive treatment for 1–3 years [120, 121]. Chief adverse effects include reduced blood counts, abdominal pain and diarrhea, and an increased risk of infections. Since the absorption of MMF is widely variable, it is desirable that its trough and AUC levels be monitored [174, 178]. Because MMF is teratogenic, contraceptive advice is required for females in and after puberty.

Mizoribine

Mizoribine, with action similar to MMF, has been examined in Japan. A double-blind placebo-controlled trial that compared 48 weeks' treatment with mizoribine (4 mg/kg/day) or placebo in FRNS or SDNS showed no difference in relapse rates [179]. A number of studies suggest that higher doses (6–10 mg/kg) of mizoribine might be more effective [180–184]. Hyperuricemia is an important side effect. A recent study showed sustained remission in 16 of 47 patients treated with mizoribine. They also found that C2/(single dose/body weight), Cmax/(single dose/body weight), and $AUC_{0–4}$/(single dose/body weight) for mizoribine were higher in those in sustained remission compared to those who relapsed [183]. Therapeutically effective concentrations were: Cmax $\geq$2 μg/mL, and AUC $\geq$10 μg. h/mL [184]. A RCT (JSKDC05, UMIN000005103) is in progress to examine the efficacy and safety of therapy with standard prednisone and high-dose mizoribine, to standard prednisone alone in patients with SSNS who relapse within 6 months of initial remission [185].

Rituximab

Approximately, 20% of patients with SSNS continue to show difficult-to-treat FRNS or SDNS during or after immunosuppressive therapies. RCTs and multiple case series suggest that treatment with rituximab, a chimeric anti-CD20 monoclonal antibody, was well tolerated and reduced relapse rates and enabled discontinuation of steroids and other medications, such as MMF and calcineurin inhibitors [186–190].

An open-label RCT in Italy showed that a single dose of rituximab and lower doses of prednisone and calcineurin inhibitors was non-inferior to standard therapy with calcineurin inhibitors and steroids in maintaining short-term remission [191]. A multicenter double-blind placebo-controlled trial in Japan examined the efficacy and safety of rituximab versus placebo in 48 children with complicated FRNS or SDNS [192]. The rituximab group received 375 mg/m^2 body surface area of the IV medication once weekly for 4 weeks. The control group received placebo at the same frequency. Prednisone and immunosuppressive drugs were gradually tapered, and patients were followed for 1 year. The 50% relapse-free period (267 vs. 101 days; HR 0.27; 95% CI 0.14–0.53, $P < 0.0001$) and the daily steroid dose was lower in those treated with rituximab than placebo (9.1±5.9 vs. 20.9±9.3 mg/m^2/day, $P < 0.0001$) up to 1 year. Most adverse events were mild; rate of serious adverse events and infusion reactions was similar. Based on these results, the Ministry of Health of Japan approved the use of rituximab for patients with complicated FRNS or SDNS in 2014. An open-label RCT in Korea showed similar results [193].

Follow-up of the above RCT [194] and cohorts show that most patients have recurrent relapses after recovery of peripheral B cell counts, notably switched memory B cells [74]. Further modifications, including repeated courses of rituximab or additional therapies, may be necessary for maintaining long-term remission. Studies suggest that repeat rituximab infusions after B cell recovery or four-times infusions at 3-month intervals induced long-term remission without serious adverse events in children with SDNS [188, 195]. However, the effect of persistent B-cell depletion on the developing immune system in children is unknown. Additionally, poor efficacy of vaccination under persistent B-cell depletion is a problem.

A cohort study in Japan suggested that maintenance therapy with MMF after rituximab administration was effective for maintaining long-term remission in children with complicated FRNS or SDNS [196]. A multicenter double-blind RCT (JSKDC07) is in progress to assess the efficacy and safety of MMF after rituximab treatment in children with complicated FRNS or SDNS.

The efficacy, safety, and cost-effectiveness of various dosing regimens should be compared to determine an appropriate rituximab treatment regimen for complicated FRNS or SDNS. In a retrospective cohort, the time to first relapse was significantly shorter in patients who received 1–2 doses of initial rituximab infusion compared with those who received 3–4 doses. However, the proportion of patients with long-term remission was not related to the number of initial doses [197]. An international large retrospective cohort study suggested that children with complicated FRNS or SDNS on low-dose rituximab without maintenance immunosuppression had the shortest relapse-free survival [198]. Further studies are required to determine the optimal dose and long-term safety of rituximab, and the role of maintenance therapy.

Rituximab has been used as a first-line treatment for uncomplicated SDNS in many centers in European countries. Although some RCTs indicated potential for rituximab as first-line drug for early uncomplicated FRNS or SDNS [199–201], further studies are required to clarify the efficacy and safety of this drug for uncomplicated FRNS or SDNS.

Rituximab is associated with serious adverse events, including fatal hepatitis from reactivation of hepatitis B virus [202], progressive multifocal leukoencephalopathy [203], pulmonary fibrosis [204], fulminant myocarditis [205], *Pneumocystis* pneumonia [206], ulcerative colitis [207], agranulocytosis [208], and hypogammaglobulinemia [209].

Late Steroid Resistance

Overall, 4–10% of children with SSNS may develop late (secondary) steroid resistance [11, 210, 211]. Patients with late steroid resistance often achieve complete remission with immunosuppressive therapy, such as calcineurin inhibitors [210]. Even in calcineurin inhibitor-resistant patients, significantly more patients with late resistance are reported to achieve remission with rituximab than those with initial steroid resistance [211, 212]. In contrast, patients with late steroid resistance experience significantly more recurrence (recurrent FSGS) in renal allografts than patients with initial steroid resistance [213].

Supportive Care

Nutrition

Nephrotic syndrome results in massive proteinuria that leads to hypoalbuminemia. In the past, high-protein diets were recommended to replace the protein lost in urine. On the contrary, studies in adults with decreased renal function suggest that protein restriction might be renoprotective and is therefore recommended [214]. In patients with pediatric SSNS, urine protein excretion decreases within 2 weeks after start of steroid therapy and serum albumin levels return to normal. Children with SSNS and normal renal function are advised protein consumption and caloric intake, as appropriate for healthy children of that age [120, 215].

Edema, Hypovolemia, and Fluid Overload

Mild edema can be managed with dietary sodium restriction to <2 mEq/kg/day and fluid restriction to two-thirds of maintenance. The use of diuretic agents or human albumin is these cases is not recommended. For symptomatic edema, the combination of sodium restriction, and use of diuretic agents or human albumin, based on evaluation of fluid status, are recommended. Clinical and laboratory investigations that aid determination of fluid status include estimation of weight, hematocrit, serum electrolytes, fractional excretion of sodium, urinary potassium index, chest radiography, and ultrasonography (Table 4) [120, 215, 216].

When circulatory failure with decreased effective circulating volume is observed (underfill), the use of IV crystalloid and/or human albumin is recommended. Patients showing normal or increased effective circulating volume (overfill) require treatment with diuretic agents, most commonly frusemide (Table 5). Combination therapy with human albumin and frusemide provides additive diuresis. IV albumin is administered cautiously, keeping in mind the risk of fluid overload [120]. An algorithm for treatment of edema in nephrotic syndrome is shown in Fig. 9 [120, 216].

Complications

Infections

Children with nephrotic syndrome are immunocompromised due to hypoproteinemia, low levels of IgG and urinary losses of opsonins, and immunosuppressive therapy. Before steroid therapy was introduced, the annual mortality rates for children with nephrotic syndrome were ~ 20%, attributed chiefly to severe bacterial infections. Therapy with corticosteroids induces remission and corrects hypoalbuminemia and anasarca, and was associated with reduction in infection-associated mortality. However, patients with FRNS or steroid resistance often require long-term treatment with steroids and immunosuppressive agents. Such patients remain immunocompromised and are at risk of severe systemic infections. Prompt diagnosis and management of these infections is an important management target; vaccination is advised where applicable [215].

Common sites of bacterial infections in children with SSNS include peritonitis, pneumonia, sepsis, and cellulitis [120, 216]. *Streptococcus pneumoniae* is the chief bacterial infection in patients with nephrotic syndrome; usual sites of infection with this organism include peritonitis, pneumonia, and sepsis [120, 215]. Gram negative bacilli, chiefly *Enterobacteriaceae*, are

Table 4 Features of hypovolemia during relapse of nephrotic syndrome

Clinical features
Abdominal pain, vomiting, lethargy
Prolonged capillary refill time; cold extremities
Tachycardia, low volume pulses
Low blood pressure; postural hypotension
Biochemical indices[a]
Elevated hematocrit
Fractional excretion of sodium <0.2%
Urinary potassium index [urine K^+/urine $Na^+ + K^+$] >0.6
High levels of plasma renin, aldosterone, vasopressin
Ultrasonography: Decreased inferior vena cava diameter, increased collapsibility index

$$\text{Fractional excretion of sodium} = \frac{\text{urine Na}^+ \times \text{serum creatinine}}{\text{serum Na}^+ \times \text{urine creatinine}} \times 100$$

[a] When analyzing urine electrolytes, the patient should be off diuretics, and on normal salt and water intake

Table 5 Diuretic agents for infants and children

Agent	Dose	Interval, h	Route	Dose in adults
Loop diuretics				
Furosemide	Neonates: 1 mg/kg/dose	12–14	IV, oral	40–80 mg QD daily or alternate days
	Infants/children: 1–4 mg/kg/day	6–12	Oral	
	1–2 mg/kg/dose	6–12	IV	
	Infuse at 0.1–0.4 mg/kg/h	Infusion	IV	
Thiazide diuretics				
Trichlormethiazide	Infants: 0.04 mg/kg/dose	12–24	Oral	2–8 mg/day at 1–2 doses
Hydrochlorothiazide	Infants: 1–2 mg/kg/day	12–24	Oral	25–100 mg QD or BID
Metolazone	0.2–0.4 mg/kg/day	12–24	Oral	2.5–10 mg QD
Mefruside	Infants: 15 mg/day for 3 years old	12–24	Oral	25–50 mg once (morning)
	25 mg/day for 7.5 years old			Or twice (morning, daytime)
	25–50 mg/day for 12 years old			
Aldosterone antagonists				
Spironolactone	Preterm infants (<32 weeks): 1 mg/kg/day	24	Oral	50–100 mg/day divided doses
	Mature infants: 1–2 mg/kg/day	12	Oral	
	Infants/children: 1–3 mg/kg/day	6–12	Oral	
Potassium canrenoate	Infants: 1–4 mg/kg/day	12–24	IV	100–200 mg IV once or twice daily
				Not exceed 600 mg/day
				Treatment period within 2 weeks
Triamterene	Infants: 1–2 mg/kg/day	8–12	Oral	90–200 mg/day, 2–3 doses

IV intravenous, QD once a day, BID twice a day

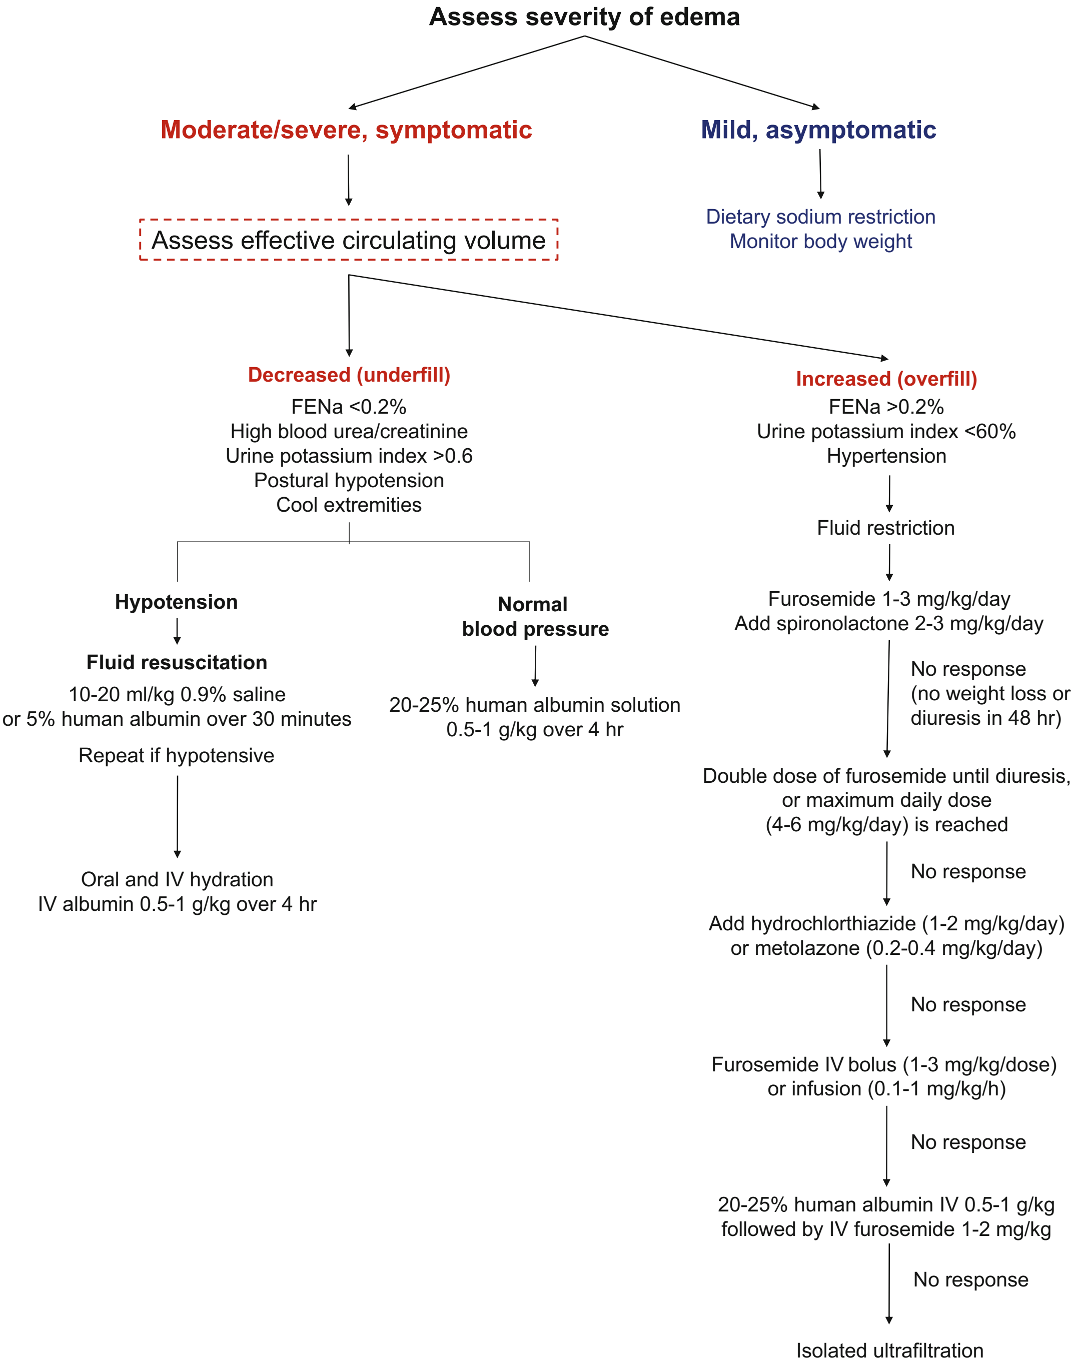
increasingly important in these children. Clinicians should be aware of the risks of mycobacterial infections (certain regions of the world), *P. jirovecii* pneumonia, and disseminated varicella.

Medications, such as cyclophosphamide, MMF, and calcineurin inhibitors, are being increasingly used in SDNS and resistant nephrotic syndrome. There are few published studies on the risk of systemic infections in patients treated with these agents in childhood. There is insufficient evidence for the efficacy of IV immunoglobulins (IVIG) and prophylactic antibiotics in patients with severely low levels of IgG and immunosuppressive therapy, respectively [215]. A meta-analysis suggested that rituximab was a risk factor for pneumocystis infection, and that prophylactic administration of cotrimoxazole is recommended [217].

Immunizations

Because acquired infection may lead to severe disease in patients with nephrotic syndrome, appropriate immunization is performed. Multiple expert groups have suggested immunization guidelines, which should be adhered [120, 215, 218]. Inactivated vaccines are preferred in patients receiving therapy with corticosteroids and immunosuppressive medications. There is no increased risk of relapses following these vaccines [219]. Inactivated vaccines are administered 6 months after the last dose of rituximab [218].

Live attenuated vaccines should not be administered to patients receiving corticosteroids or other immunosuppressive agents. However, the decision to use attenuated vaccines may be determined on a case-by-case basis. A study in



Assess severity of edema

followed by IV furosemide 1-2 mg/kg
No response
Isolated ultrafiltration

Fig. 9 Management of edema in nephrotic syndrome. Patients with mild edema are managed with salt restriction; prednisone therapy is associated with spontaneous diuresis. Hypovolemia should be excluded (Table 4) before considering therapy with diuretics. Oral furosemide is the diuretic of choice; patients receiving therapy with furosemide for >48 h should additionally receive a potassium-sparing diuretic. Edema refractory to furosemide therapy may be treated with additional thiazide diuretics or IV furosemide, as bolus and/or infusion. Combination therapy with IV albumin (20%) and furosemide enables diuresis in patients refractory to the above measures. IV albumin carries the risk of fluid overload and pulmonary edema in patients with renal dysfunction. Patients with features of

Japanese patients, treated with immunosuppressive agents but currently normal cellular and humoral immunologic features, showed that immunization with live attenuated vaccines was immunogenic and safe [220]. Vaccination of family members is recommended. In cases where a patient has been in contact with a patient with varicella, prophylaxis with acyclovir or valaciclovir is advised [120, 221].

Thromboembolism

The risk of thromboembolism is variable, ranging from ~3% in children to ~20% in adults; children older than 12 years have a comparatively higher risk [222]. Venous thrombosis is more common than arterial thrombosis, and deep venous thrombosis, cerebral venous thrombosis, and pulmonary embolism account for the majority. The complication is chiefly observed in patients with frequent relapses, steroid dependence or steroid resistance. However, many patients show this complication early in the course of illness, more commonly during relapse than in remission [222]. Factors associated with this complication include increased platelet count, increased platelet aggregation, urinary loss of anticoagulant factors (anti-thrombin-III), and increased biosynthesis of coagulation factors (fibrinogen). The former two predispose to arterial, and the latter two to venous thrombosis. Prolonged bed rest, hypovolemia with hemoconcentration, infections, nephrotic range proteinuria, central venous catheters, and genetic variations favoring coagulation further increase the risk. Patients with marked hypoalbuminemia (<2 g/dL), low anti-thrombin-III (<70%), and high fibrinogen (>600 mg/dL) should be observed for the complication [215, 222]. If a thrombus is detected in a medium or large vessel, anticoagulation measures are instituted. Unfractionated or low-molecular-weight heparin is administered initially, followed by warfarin for 3–6 months. There is insufficient evidence for primary prophylaxis against venous thromboembolism in children with relapsing nephrotic syndrome.

Dyslipidemia

Nephrotic syndrome is associated with dyslipidemia. Hypoalbuminemia increases hepatic synthesis of lipoproteins, particularly low-density lipoprotein (LDL) and very low-density lipoprotein (VLDL) that increase total cholesterol, triglycerides, LDL cholesterol, and lipoproteins [223]. In SSNS, dyslipidemia rapidly normalizes during remission and is therefore unlikely to have long-term consequences, except for anecdotal reports on atherosclerosis and coronary artery disease. Since some patients might have additional cardiovascular risk factors (hypertension, obesity, insulin resistance), the potential risk of dyslipidemia cannot be ignored [216]. Use of lipid-lowering agents for dyslipidemia is not recommended, unless there is persistent proteinuria with extremely high levels of LDL cholesterol and triglycerides. Therapy with statins may be instituted in specific patients over 8-year-old, with monitoring of liver functions and creatinine kinase [223, 224].

Osteoporosis

Measurement of bone mineral density (BMD) using dual-energy X-ray absorptiometry is recommended for children with FRNS or SDNS [225, 226]. Bisphosphonates were reported to increase BMD during steroid therapy in children with nephrotic syndrome [227]. However, bisphosphonates may also reduce bone strength by inhibition of bone remodeling. A RCT in children with nephrotic syndrome, including patients with relapsing disease, suggested that administration of vitamin D and calcium supplements at initiation of corticosteroid therapy suppressed the decrease of BMD. However, the study also showed significant increase in levels of serum and urine calcium, leading to a risk for hypercalciuria and urolithiasis [228]. Collectively, there is insufficient evidence on bisphosphonates, vitamin D,

Fig. 9 (continued) hypovolemia require bolus(es) of normal saline if hypotensive, followed by oral and IV hydration, and IV albumin (20%) infused over 2–4 h. FENa fractional excretion of sodium; urine potassium index $UK^+/UK^+ + UNa^+$ (Modified from Indian Pediatrics 2021) and calcium for therapy of steroid-induced osteoporosis in children. The efficacy and safety of vitamin K, selective estrogen receptor modulators, and parathyroid hormone is not established.

Long-Term Outcome

About 25% patients experience only one episode of the disease and are cured after the initial course of corticosteroids. Fifteen to 20% patients experience relapses several months after stopping the treatment and a cure takes place after three or four episodes. The remaining 40–50% patients show either frequent relapses or steroid dependence. Patients with SDNS often have a prolonged course of their illness. However, if they continue to be steroid sensitive, the risk of progressive kidney disease is minimal.

There are few studies regarding the long-term outcome in of patients with SSNS starting during childhood. Studies from the 1980s reported that no more than 10% of children had further relapses in adulthood [229, 230]. More recent surveys indicate a relapse rate, after 18 years of age, to vary between 27% and 42% [231–233]. Risk factors for relapses during adulthood include a young age at onset, high number of relapses during childhood, and the need for use of alkylating agents and/or cyclosporine. Long-term therapy with calcineurin inhibitors may be detrimental to kidney function in adults.

The long-term side effects of treatments given to children have changed over the years. While corticosteroids and alkylating agents were the only drugs available for treatment of idiopathic nephrotic syndrome 30 years ago, there have been major changes in the approach for management of patients with FRNS with the availability of levamisole, mycophenolate mofetil, calcineurin inhibitors, and rituximab. Long-term steroid therapy started in childhood is associated with a number of adverse effects, mainly short stature, weight excess, osteoporosis, and cardiovascular events. Most recent studies on the final height showed an average height in adulthood close to the genetic target height and no detrimental effects of steroid therapy [233–235]. This may be due to the larger use of steroid-sparing agents when statural growth is impaired during childhood. The incidence of overweight in adulthood varies among the long-term cohorts, ranging between 19% and 35% [233]. However, these reports found no correlation between the body mass index and the cumulative dose of steroids or number of relapses. The incidence of overweight in these patients may be close to that observed in the general population.

Osteoporosis, associated with a risk of fractures, has been observed in significant proportion of adult patients, including patients who were still relapsing in adulthood [231, 233, 236, 237]. Long-term corticosteroid therapy may be associated with cataracts in ~10–33% children and 6–20% patients in long-term cohorts [234, 236–238]. A high incidence of systemic hypertension is found in adult patients receiving therapy with corticosteroids and/or calcineurin inhibitors [234]. The cardiovascular risks of long-term therapy with steroids, hypertension and dyslipidemia in patients with nephrotic syndrome are not known. Long-term toxicity of alkylating agents includes gonadal toxicity [239]. The risk of sterility is greater in boys than in girls. The cumulative threshold dose above which oligo/azoospermia may be feared is between 150 and 250 mg/kg [240].

SSNS is a self-limiting illness with the majority of patients outgrowing the disease by puberty. Review of information from multiple cohorts shows a considerable risk of disease persistence and long-term complications of the disease and/or its therapies [241]. Given these risks, it is advised to transfer care of adolescents with relapsing disease to “adult” nephrologists at the appropriate time. National and international guidelines advocate for smooth transition, with emphasis on shared clinics and consideration of patient and parent perspectives.

Abstract

Historically, the classification of steroid-resistant nephrotic syndrome (SRNS) was based on histopathology alone, with minimal change disease and especially focal segmental glomerulosclerosis (FSGS) being the dominant lesions. Nowadays, genetic forms are differentiated from nongenetic forms. The latter can be broadly divided into two groups: (1) idiopathic SRNS is considered to be mediated by a (yet unidentified) permeability factor and (2) secondary forms of FSGS either resulting from a maladaptive response of podocytes to conditions promoting

hyperfiltration (obesity, acquired solitary functional kidney, or uncontrolled hypertension) or distinct podocyte injury (e.g., viral infections, exposure to toxins or drugs). Histopathology is still an important diagnostic tool and can help to assess prognosis and recent studies have shown its potential as research tool in clarifying pathogenesis. Large studies and registry data have shown that overall prognosis of SRNS has improved in recent years because potent immunosuppressants are available. Especially the use of calcineurin inhibitors (in combination with steroids and RAAS inhibitors) is now recommended as first-line treatment option. For treatment of refractory patients, B-cell depleting antibodies (e.g., rituximab) and mycophenolic acid or pulse methylprednisolone are an option. Other interventions may be effective in individual patients. Unfortunately, patients unresponsive to treatment have a high risk of developing end-stage kidney failure and have a considerable risk of disease recurrence after kidney transplantation.

Idiopathic SRNS · Secondary SRNS · Glomerular permeability factor · Pathophysiology · Histopathology · Immunosuppression · Calcineurin inhibitors · Recurrence · Columbia classification · Genetic SRNS · Rituximab · Mycophenolic acid · Methylprednisolone

Historically, the classification of the primary idiopathic nephrotic syndrome was based on histopathology alone [1]. Minimal change disease (MCD) and focal segmental glomerulosclerosis (FSGS) are the most frequent causes. Studies by the ISKDC, however, have shown that biopsies in patients responding to prednisone revealed MCD in more than 85% [2]. Thus, nowadays a biopsy is usually performed only in children with steroid-resistant nephrotic syndrome (SRNS) or when features suggesting another diagnosis are present (laboratory abnormalities, renal insufficiency, age >10 years, etc.). In recent years, more and more monogenetic forms of idiopathic SRNS have been described [3]. Approximately 80 different mutations are known and approximately 30% of SRNS patients are affected; some authors view genetic SRNS as a secondary cause [4, 5]. Response to immunosuppression, prognosis, and risk of recurrence after renal transplantation are different in genetic SRNS compared to those with acquired, i.e., nongenetic steroid-resistant nephrotic syndrome, although some overlap exists.

Pathophysiology

Studies from the early 1990s provide insights into the pathogenesis of FSGS. Once thought to be inactive cells, podocytes act as a buttress to the pressures within the glomerulus. Outward bulging of the glomerular basement membrane (GBM) initiates the well-described first committed step of focal glomerulosclerosis [6]. Podocyte injury leads to cell body attenuation, foot process effacement, pseudocyst formation, and microvillus transformation in the early phase of FSGS; interstitial fibrosis with tubular atrophy follows later [7, 8]. These common terminal lesions often provide little insight into the precedent injury. The identification of known podocyte-specific mutations has partially elucidated the mechanisms leading to the characteristic focal and segmental lesions in genetic forms of SRNS (see ▶ Chap. 10, "Genetic Basis of Nephrotic Syndrome").

Nongenetic forms of FSGS can be broadly divided into two kinds of disorders [9]. While idiopathic FSGS is considered to be mediated by an unidentified permeability factor, secondary forms of FSGS result from a maladaptive response of podocytes to conditions that either promote hyperfiltration, such as obesity, acquired solitary functional kidney, and uncontrolled hypertension, or lead to podocyte injury, such as viral infections (hepatitis B and C, parvovirus, HIV), exposure to toxins (e.g., heavy metals) or drugs (e.g., anti-VEGF monoclonal antibodies, lithium and interferon) [4].

Idiopathic FSGS

The term "idiopathic" FSGS describes a phenotype of SRNS in which FSGS lesions on the kidney biopsy are believed to be caused by a presumptive permeability factor, after other secondary factors have been excluded. Until the identification of such a permeability factor is universally accepted, the condition continues to be termed "idiopathic," harmonizing with global efforts to move away from the term "primary FSGS." Where the renal biopsy is associated with a FSGS lesion, with or without the presence of widespread podocyte foot process effacement, and a pathophysiologic mechanism is established (collectively known as "secondary FSGS"), treatment is often targeted at the underlying disease process. For this group, the term "secondary FSGS" will continue to be used, with the underlying cause explicitly articulated as far as possible, e.g., "secondary FSGS due to maladaptive responses" or "secondary FSGS due to other primary glomerular disease" [4].

Available information on the pathogenesis of idiopathic SRNS and FSGS nephrotic syndrome has led to various hypotheses, which are summarized in Fig. 1. A major breakthrough in understanding the pathogenesis of idiopathic SRNS was the identification of mutations in approximately 80 genes encoding structural elements of the slit diaphragm. The disease in the majority of the remaining cases is assumed to be mediated by immunological perturbations leading to generation of a circulating glomerular permeability factor. An imbalance between T helper 1 (Th1) and Th2 cytokines, increased Th17 versus T regulatory activity and enhanced urinary CD80 excretion by podocytes, chiefly reported in patients with steroid-sensitive nephrotic syndrome, require closer evaluation in SRNS [10]. A "circulating factor" hypothesis for SRNS is supported by observations that FSGS recurs in the allograft within hours of transplantation in 30–50% patients, resolves with plasmapheresis or following retransplantation in another individual, and by experimental data in which nephrotic plasma induces proteinuria in rats, increases permeability in isolated glomeruli, and induces cytoskeletal changes and/or cytoplasmic translocation of key slit diaphragm proteins [11, 12]. Investigations using various techniques indicate that the factor is absent from the lipid fraction, is denatured by heat, is destroyed by protease digestion, and weighs 30–50 kDa, indicating that it may be a low molecular weight protein. However, thus far, none of the reported circulating permeability factor candidates have been independently validated in primary FSGS [13]. Evidence favoring or disputing various candidate circulating factors have been published [11, 12, 14–16]. Within the span of a decade, soluble urokinase-type plasminogen activator receptor (suPAR), that had generated widespread excitement among researchers as a diagnostic biomarker representing the permeability factor in FSGS, has since been repurposed as a prognostic biomarker for chronic kidney disease (CKD) [17]. Cardiotrophin-like cytokine factor 1 (CLCF-1), a member of the IL-6 cytokine family that decreases nephrin expression in podocyte culture, was identified in the plasma of patients with FSGS, with concentrations in those with recurrent FSGS being up to 100 times that of normal subjects [11]. None of the current candidates have unequivocal evidence for role as the circulating factor. In addition, there could be different circulating factors in individual patients.

Maladaptive Injury Response

Several processes associated with intraglomerular hypertension (increased single-nephron GFR) are described to cause glomerular hypertrophy and podocyte activation, hypertrophy, stress, and denudation, leading to extracellular matrix deposition and glomerular sclerosis [18].

Obesity-Related Glomerulopathy

An association between obesity and nephrotic range proteinuria was first described in 1974 [19]. Various factors are implicated in the pathophysiology of obesity-induced glomerulopathy [20]. While increased renal plasma flow and hyperinsulinemia-induced efferent arteriolar

Fig. 1 Prevailing hypothesis in the pathogenesis of idiopathic nephrotic syndrome of childhood. Schematic view of podocyte foot process demonstrates components of the slit diaphragm complex, formed by nephrin, Neph1, and podocin, and the actin cytoskeleton, which also receives inputs from the basolateral domain of the foot process, containing the a3b1 integrins and a and b dystroglycans. The dominant paradigm in nephrotic syndrome is an imbalance between T helper 1 (Th1) and T helper 2 (Th2) cytokines, and that a cytokine soluble mediator increases glomerular permeability. Non-cytokine molecules suggested as mediators include soluble urokinase plasminogen activator receptor (suPAR) that activates podocyte b3 integrin signaling to integrin-linked kinase (ILK), circulating proteases that phosphorylate vasodilator-stimulated phosphoprotein (VASP), vascular endothelial growth factor, and angiopoietin-like-4 (ANGPTL4). Signaling through nuclear factor kappa B (NF-jB) and toll-like receptor (TLR)-mediated pathways may polarize adaptive immune responses toward Th2 cells or directly increase CD80 expression in podocytes. An imbalance of Th17 and T regulatory responses might allow persistent CD80 activation on podocytes and/or helper responses. MicroRNAs may influence glomerular permeability through changes in gene transcription. Therapeutic agents are known to have direct effects on podocytes: glucocorticoids (G) on gene expression, calcineurin inhibitors (C) on stabilization of synaptopodin (S) or inhibition of TRPC6 channel, binding of rituximab (R) to the SMPDL-3b protein and of abatacept (A) to CD80. constriction lead to intraglomerular hypertension, hyperinsulinemia enhance the synthesis of growth factors like insulin-like growth factor 1, which promote glomerular hypertrophy. Elevated plasma leptin enhances transforming growth factor-β1 production that upregulates profibrotic pathways [21].

Low Nephron Mass

The impact of fetal programming on the development of adult disease has been of interest ever since Barker hypothesized that intrauterine growth restriction (IUGR), indicated by low birthweight, predisposes individuals to type 2 diabetes, hypertension, dyslipidemia, and cardiovascular disease in adult life. The strong epidemiologic relationship between intrauterine growth retardation and adulthood hypertension led Brenner to posit an inverse relationship between nephron mass and hypertension [22]. Birth weight is a strong determinant of nephron number and glomerular size [23, 24]. Data from infant autopsies suggests that newborns weighing less than the 10th percentile for the gestational age or below 2500 g have smaller kidneys, fewer nephrons, and larger glomerular volume than those with normal weight for age [86]. Since nephrogenesis in humans is completed around 36 weeks of gestation, prematurity also leads to low nephron number (oligonephronia) [25]. Overall, while IUGR appears to have greater impact on nephron mass than prematurity, both contribute to risk of proteinuric CKD. Several cohort studies have demonstrated disproportionate prevalence of albuminuria or biopsy-demonstrated FSGS in patients with low birth weight or IUGR [26].

Infection-Associated FSGS

Several viruses and parasites are known to be associated with FSGS. Proposed mechanisms include direct infection of podocytes and, rarely, activation of the innate immune pathways that lead to podocyte injury. Evidence of direct infection of the podocyte is demonstrated for HIV-associated nephropathy (HIVAN), where podocyte-restricted expression of HIV genes in transgenic mice was associated with collapsing glomerulosclerosis [27]. Chronic hepatitis B virus (HBV) infection may present with several different glomerular pathologies, ranging from primarily nephrotic conditions like minimal change disease (MCD), FSGS, and membranous nephropathy, to inflammatory conditions such as membranoproliferative glomerulonephritis and IgA nephropathy. Reduction in HBV viremia is associated with remission of proteinuria. Identification of viral DNA in urinary podocytes isolated from patients with collapsing variant of FSGS and chronic HBV infection indicates podocytes as a direct target for injury [28].

Parvovirus B19 DNA has been identified by in situ hybridization in kidney endothelial and visceral and parietal epithelial cells in various kidney lesions, including collapsing and idiopathic forms of FSGS, membranous nephropathy, and MCD [29] The histological picture mimics characteristic glomerular changes of HIVAN, including increased size and number of visceral epithelial cells, cytoplasmic vacuoles, and protein absorption droplets [30]. Parvovirus DNA was demonstrated in podocytes as well as tubular and parietal cells in cases with ultrastructure confirming morphologically altered podocytes [31], suggesting that, similar to HIVAN, parvovirus related collapsing FSGS reflects direct podocyte injury. In contrast, acute CMV infection, rarely associated with collapsing FSGS, is postulated to induce FSGS lesions through generation of a local interferon response, rather than direct viral cytopathic effect [32]. Acute EBV infection is also rarely described with FSGS; however, viral DNA has been consistently localized to kidney tubules rather than the glomerulus. Viral-associated kidney diseases are discussed elsewhere (▶ Chap. 27, “Viral Infections and the Kidney”). Recently, infections with COVID-19 have been associated with development of FSGS [33].

Toxic Exposures

Several case reports and case series highlight an association between nephrotic syndrome and exposure to heavy metals like mercury, copper, cadmium, and lead [34]. These associations are substantiated by in vitro and animal models demonstrating podocyte injury and proteinuria in response to exposure to heavy metals.

Drug-Induced Podocytopathy

Several medications have been associated with the development of FSGS. A collapsing variant of FSGS was first described following therapy with bisphosphonates in 2001 [35], with characteristic abundance of cells in Bowman space, which appeared to derive from parietal epithelial cells [36]. Monoclonal antibodies that inhibit the function of vascular endothelial growth factor (VEGF, e.g., bevacizumab, axitinib) induce proteinuria in a dose-dependent manner. VEGF is considered critical for glomerular endothelial cell and podocyte cross-talk, which is necessary to maintain normal podocyte structure. Hence, VEGF our leads to swelling and detachment of glomerular endothelial cells, vacuolization of endothelial cells, disruption of slit diaphragms, and downregulation of nephrin [35, 37]. Anthracyclines, like adriamycin and doxorubicin, are reported to lead to collapsing FSGS [38], and their injection in mice provides a reliable in vitro model for proteinuric disease [39, 40].

Therapy with interferon α, β, and γ is associated with minimal change, FSGS, or collapsing FSGS [41, 42]. While the precise mechanism is unclear, interferons may affect podocyte proliferation, cellular metabolism or oxidative capacity, and/or increase the expression of major histocompatibility complex (MHC) class II antigens that increase production of interleukin (IL)-6 or −13, leading to macrophage activation [43]. The long-term use of anabolic steroids was associated with FSGS in nine of ten bodybuilders, along with glomerulomegaly in four cases. Podocyte injury was considered secondary to post-adaptive glomerular changes driven by increased lean body mass and/or direct nephrotoxicity of anabolic steroids [44]. Heroin-associated nephropathy, reported in 1970s–1990s in IV drug abusers, was characterized histologically by either FSGS or amyloidosis; however, causality was not confirmed since contaminants (e.g., scopolamine), concomitant viral infections (e.g., HCV or HIV), and most recently, *APOL1* genetic variants are also implicated [45]. Chronic lithium toxicity, which typically presents with nephrogenic diabetes insipidus, and is histologically characterized by chronic tubulointerstitial nephropathy and distal tubular cysts, may uncommonly be associated with minimal change disease or FSGS [46, 47]. Pathogenesis might involve lymphocyte-derived factors that alter the filtration barrier or interactions of lithium cations with the negatively charged GBM [48]. While some cases with FSGS have glomerulomegaly, suggesting secondary FSGS, others have features consistent with a primary podocytopathy. Other drugs associated with nephrotic range proteinuria are nonsteroidal anti-inflammatory drugs and cyclooxygenase-2 inhibitors (minimal change disease) and sirolimus (FSGS) [49].

Pathology

Minimal change disease (MCD) and focal segmental glomerulosclerosis (FSGS) are the most frequent causes of nephrotic syndrome in children. Patients with MCD usually respond to glucocorticoids, while FSGS accounts for approximately 90% of SRNS; Therefore, FSGS and SRNS are often referred to synonymously. It should be remembered, however, that patients with SRNS may have MCD, although some authors regard this as yet undiagnosed FSGS. Lastly, some patients respond to corticosteroids initially but then develop secondary steroid-resistance and may have MCD or FSGS on kidney biopsy.

In FSGS, other pathophysiological factors are causative and multiple etiologies have been described above. However, in the majority of nongenetic SRNS cases, the underlying mechanism is unknown [9]. Therefore, a histopathological diagnosis of FSGS (and MCN) has to be viewed as a lesion or histological pattern and not as a disease itself as findings are nonspecific. Although some histopathological variants correlate with certain etiologies, no systematic studies have been performed in order to address differences among these, e.g., between genetic and nongenetic (especially immunological causes). Patients with ACTN4 mutations demonstrate distinctive biopsy features suggestive of maladaptive FSGS [9]. Nevertheless, renal biopsy is still an important tool in the evaluation of a child with SRNS and specific clues can be provided by light microscopy, immunofluorescence, and electron microscopy.

Histopathology (Fig. 2)

Because most patients with nongenetic SRNS have MCD or FSGS, focus will be on these two entities. In MCD, **light microscopy** will reveal normal-appearing glomeruli with normal cellularity and capillary walls. Mild focal mesangial predominance may be seen; if more than 3 mesangial cells/per mesangial area away from the vascular pole region are present in at least 80% of

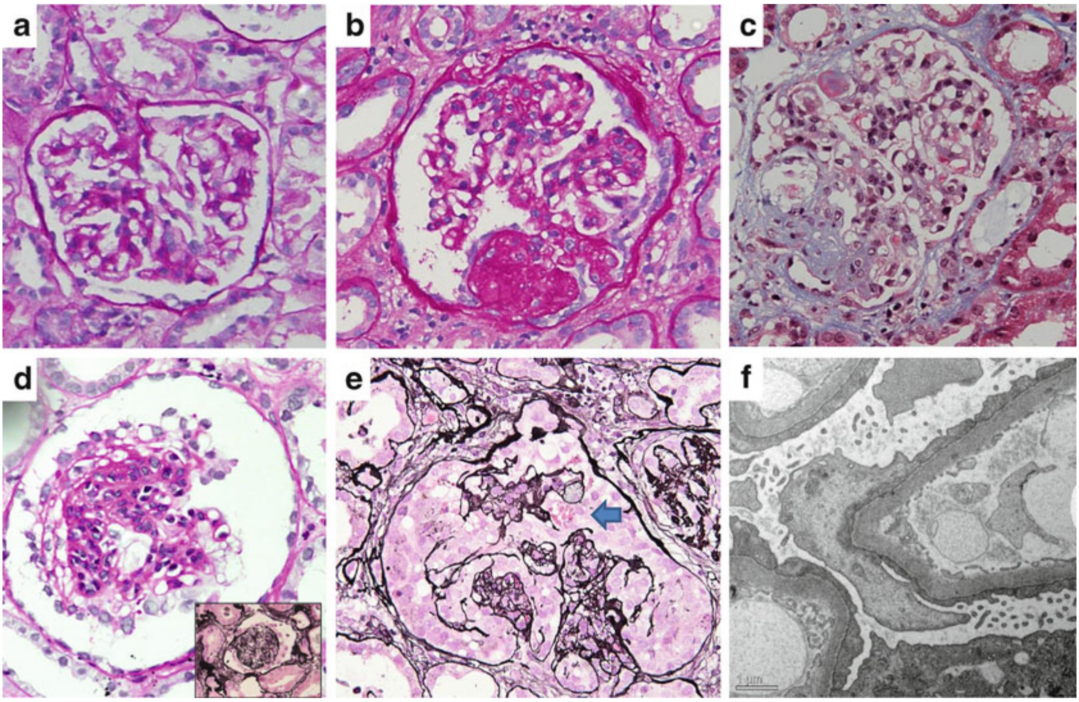

Fig. 2 (**a**) Minimal change: Morphological unremarkable glomerulus (periodic acid-Schiff; 20×). (**b**) Focal segmental glomerulosclerosis not otherwise specified (FSGS-NOS): The sclerotic segment at 6 o'clock is "crowned" by epithelial cells. Note the irregularly thickened Bowman capsule (periodic acid-Schiff; 20×). (**c**) FSGS-NOS: The collagenized sclerotic segment at 8 o'clock stains blue, while peripheral hyalinosis noted at 11 o'clock position stains pink (Masson trichrome; 20×). (**d**) Diffuse mesangial sclerosis: The mesangium appears sclerotic and hypercellular without open capillary loops and with variable overlying visceral epithelial cell proliferation (periodic acid-Schiff; 20×). Inset shows classic mesangial knotting or "yarn ball" appearance and crowning with a single layer of visceral epithelial cells (Jones methenamine silver; 20×) (**e**) Collapsing glomerulopathy: The glomerular tuft is globally collapsed or imploded by markedly hypertrophic and hyperplastic visceral epithelial cells, displaying conspicuous nucleoli and protein resorption droplets (arrow) (Jones methenamine silver; 20×) (**f**) Transmission electron microscopy, in all primary podocytopathies, is characterized by diffuse foot process effacement, actin condensation, and microvillous transformation, the ultrastructural hallmarks of podocyte injury (uranyl acetate-lead citrate; 2550×). glomeruli, this is termed diffuse mesangial hypercellularity variant of MCD.

In FSGS of the usual, not otherwise specified type (nos), a segmental increase in the glomerular matrix with obliteration of the capillary lumina is seen [50]. The first characteristic is that glomerular lesions in FSGS affect only some of the glomeruli in early stages of the disease. Of note, in advanced FSGS, the lesions may rather involve all glomeruli. Usually juxtamedullary/inner cortex glomeruli are affected first. Detailed serial section studies show that even though the extent of segmental lesions increases with such three-dimensional analysis, the lesions remain focal, i.e., sparing some of the glomeruli, even in patients with moderately advanced disease [51]. As focality is more pronounced in children, comprehensive sampling is critical especially in this age group. As a second characteristic, the sclerosis is segmental, affecting only a part of the glomerular tuft. In early stages, capsular adhesions without underlying abnormalities in the tuft may be present and indicate a diagnosis of early FSGS rather than MCD. Nonsclerosed glomeruli show significant glomerular hypertrophy in FSGS, compared to age-matched controls. In some instances, the whole tuft is affected by sclerosis (focal and global sclerosis). Global glomerulosclerosis in an obsolescent pattern, i.e., the tuft condensed and globally sclerosed with a corona of matrix filling in Bowman's space, is a nonspecific lesion, present in normal individuals and increasing with age. Even young children may thus show occasional global glomerulosclerosis in this pattern, and this does not per se indicate a diagnosis of FSGS.

Sclerosis may progress and plasma insudation may be present, evident by glassy, smooth eosinophilic and PAS-positive material (hyalinosis). This lesion is nonspecific and may be seen in any sclerosing injury. There may be vacuolization of podocytes. Detachment of podocytes from the basement membrane is typical in children, best viewed by electron microscopy. Mesangial hypercellularity may be present in children with FSGS, but is not per se sufficient to diagnose FSGS rather than MCD (see above) if segmental sclerosing lesions or adhesions are not present. Tubular changes are often present and may show patchy atrophy, interstitial fibrosis, and lymphocytic infiltration correlating with glomerular pathology. Tubulointerstitial fibrosis in the absence of segmental sclerosing lesions raises suspicion for unsampled FSGS. Additional serial sectioning may then be undertaken to hunt for diagnostic glomerular lesions. Lipids and protein droplets may be present in proximal tubular cells.

Immunofluorescence

Immunofluorescence is usually negative, although mild staining for C3, C1q, IgM, or IgA may occur in mesangial areas in MCD, particularly if mesangial hypercellularity is present, and in sclerosed areas with or without hyalinosis in FSGS. The presence of more than trace amounts of IgG and IgA is suggestive of an immune complex process rather than just podocyte injury, especially if cellular proliferation is also present. The presence of IgM staining by IF but without deposits by electron microscopy was associated in some early studies with poor response to corticosteroids and some authors suggested the term IgM nephropathy. More recent work suggested that IgM deposition is more frequent in FSGS than in MCD but it has also been described in IgA nephropathy and in areas of mesangial increase in MCD, thus being nonspecific. Deposition of IgM, which is a large molecule, may be due to trapping in an injured glomerulus; others have suggested that IgM binds to neoepitopes in the mesangium after nonimmune injury resulting in complement activation [52]. Therefore, IgM nephropathy remains a controversial entities and more work has to be done to define the distinct pathogenesis and clinical implications of these lesions.

In some biopsies of NS patients, staining for C1q is dominant greater than other components, with mesangial and occasional subendothelial deposits on electron microscopy. This constellation of findings has been termed C1q nephropathy. Systemic lupus erythematosus and other disorders of complement activation need to be excluded, as these may also lead to C1q deposits. This lesion is of unknown etiology and shows variability both histologically as well as clinically, including therapeutic responses and prognosis. The light microscopic pattern may show no lesions, or proliferative lesions, or segmental sclerosis, and has been correlated with clinical course. Patients with minimal lesions by light microscopy have done well, whereas those with segmental sclerosing lesions have followed a course similar to FSGS, and those with proliferative lesions behaved more like immune complex disease. In a series of 12 pediatric patients with C1q nephropathy, light microscopy showed FSGS with or without diffuse mesangial proliferation in 6, MCD in 4, and focal proliferative glomerulonephritis in 2 patients. While C1q deposits were found in all patients, electron microscopy revealed visible deposits only in nine cases. The response to steroids was variable and steroid resistance was associated with poor prognosis [53].

The involvement of the complement system in FSGS is also supported by a recent study demonstrating Cd4 positive staining in 73% of FSGS patients compared to 21% of MCN and 10% of controls [54]. C4d is generated by the activation of the classical and lectin pathways, and hence its presence can point to the activation of either of these pathways. Interestingly, fibrosis was absent in 42% of patients with C4d+ staining and was more prevalent in patients who developed recurrent FSGS after transplantation. In rats, CD4 staining was frequently positive at the onset of proteinuria and before the FSGS lesions developed, suggesting a role of complement activation in the early stages of FSGS. In another study, mesangial C4d deposition was an independent predictor of disease progression [55]. More studies are warranted to define the role of the complement system in FSGS.

Electron microscopy

Electron microscopy plays an important role in the investigation of patients with SRNS since ultrastructural changes at the podocyte level are present irrespective of the etiology or changes on light microscopy. EM also is also an important tool to exclude immune complex disorders and metabolic causes such as amyloidosis or Fabry disease. Some genetic forms of SRNS such as COL4 mutations are associated with distinct basement membrane alterations, i.e., thinning of the glomerular basement membrane early, with later segmental thickening and basket-weaving (see chapter on Alport/thin basement membrane lesion) which are assessed by EM. Foot process effacement (FPE) is extensive in MCD and so-called primary FSGS, even in nonsclerosed glomeruli; this may be the only morphological lesion in MCD and correlates with the degree of proteinuria. Of note, occasionally a biopsy is planned for a patient with relapsing NS, and corticosteroid treatment is initiated before biopsy. If the patient has a partial response by the time of biopsy with decreased proteinuria, there may be limited or no FPE on biopsy, with no segmental lesions by LM. In this clinical context, with a patient who had NS some days or weeks early, who has been treated, this constellation of clinicopathologic findings is consistent with treated/responsive MCD.

Global FPE and foot process width are overall greater in primary idiopathic FSGS compared to maladaptive FSGS. However, extensive FPE may be seen in secondary FSGS, particularly if the glomerulus assessed by EM at some level has segmental sclerosis. Thus, FPE less than around 50% is not consistent with untreated primary FSGS, and extensive FPE may represent either primary or secondary forms of FSGS. Sclerotic lesions show a wrinkled basement membrane, obliteration of the capillary lumen and may show hyaline (see above), seen by EM as paramesangial and subendothelial, finely granular, osmiophilic densities. The presence of lipid droplets, their location in sclerotic areas, and correlation with the EM scout section will avoid the mistake of confusing these with immune complex deposits. Foamy macrophages in sclerosed areas may contain protein and lipid droplets.

The Columbia Classification of FSGS and Clinical Relevance

For clinicians, the development of the Columbia classification of FSGS has helped to translate complex histopathological findings into clinical practice [56]. It shows good reproducibility among independent observers and includes five variants:

1. Most frequent is the classical or “not other specified” (nos) FSGS.
2. FSGS with lesions at the vascular pole of the glomerular tuft (perihilar type).
3. The cellular variant (podocyte hyperplasia, endocapillary hypercellularity, foam cells, and leucocyte infiltration).
4. Lesions at the tubular pole (tip lesion).
5. The collapsing variant.

It should be noted that the segmental lesions may show mixed appearances in a given biopsy, and the Columbia classification thus proposed a hierarchical classification schema. Further, with progressive scarring, all patterns may develop into progressive scars of nos type, or global sclerosis. Further, none of the patterns are unique for so-called primary FSGS, and insights have emerged suggesting specific etiologies linked to specific morphologic class. Several retrospective studies have correlated clinical outcome with the Columbia histopathological class. Overall, the tip lesion often has a favorable outcome, similar to MCD, with response to therapy, contrasting the much worse outcome seen with the collapsing variant. The collapsing variant is often associated with infections, such as HIV, parvovirus B19, CMV, and now even recognized to occur with COVID-19 [33]. Drugs may also cause this lesion, including, e.g., bisphosphonates, interferon, anabolic steroids, TNF alpha antagonists, and others. Idiopathic collapsing glomerulopathy predominates in patients of Black African ethnicity especially those with APOL1 risk allele variants (G1, G2, compound heterozygous or homozygous) and is associated with a poor prognosis. Recurrent FSGS in the transplant generally, but not always, shows fidelity to the pattern of the original native kidney lesion [57].

Of interest, in the NIH multicenter trial of steroid-resistant FSGS patients, 138 patients age 2–38 years were randomized to cyclosporine or mycophenolate mofetil with dexamethasone [58]. Classical (nos) FSGS was the most frequent lesion (68%) followed by collapsing (12%), tip (10%), perihilar (7%), and the cellular type (3%). Proteinuria in (nos) FSGS was more likely to be subnephrotic. Tip or collapsing lesions were more frequent in teenagers and adolescents and subjects with these variants had greater proteinuria and hypoalbuminemia than those with classical FSGS. The tip variant was more common in whites and was associated with lower injury scores and rate of progression. In contrast, the collapsing variant, which was more frequent in African Americans, carried an unfavorable prognosis. The rate of progression to end-stage kidney disease was highest in collapsing (47%), intermediate in NOS (20%), and lowest in the tip variant (7%). This is notable, as these tip patients were nonresponsive to steroids, and thus not representative of typical tip lesion patients who respond to immunosuppression. Unfortunately, this study did not include tests to diagnose genetic causes or APOL1 polymorphisms.

A recent study evaluated the prognosis of collapsing versus classical (nos) FSGS controlling for treatment [59]. Of 187 patients, 61 had collapsing and 126 not otherwise specified lesions. Despite having lower eGFRs and higher levels of proteinuria, patients with collapsing FSGS had similar outcomes in terms of patients achieving remission or those progressing to end-stage renal disease. Although patients with collapsing FSGS had higher levels of proteinuria and a lower eGFR, the outcome was similar between groups, regarding proportion of patients reaching remission or end-stage renal disease. Thus, controlling for severity of disease at presentation, collapsing was not worse – the challenge being that collapsing patients in multiple other series had worse features at presentation. The challenge is to identify and diagnose such patients at earlier time points. The positive impact of early treatment has also been demonstrated in recurrent FSGS after transplantation, where new treatment options initiated at very early time of recurrence have improved prognosis.

Systematic evaluation of certain histopathological findings is difficult to perform or at least time-consuming. This, for instance is especially true for distinct features in FSGS, e.g., glomerular hypertrophy and tubular fibrosis. Both have been suggested as markers of an unfavorable prognosis, but no large studies are available that evaluated the prognostic relevance in details. This problem could be resolved in the near future with the help of deep learning. Renal pathology is just entering the era of digital pathology and computational image analysis, allowing for tissue-interrogation not previously possible.

Deep learning-based segmentation of histological structures has been performed. In a recent study by Jayapandian et al. [60], 125 renal biopsies from MCNS patients collected in the Neptune database were analyzed. They demonstrated that periodic acid-Schiff staining yielded best concordance between pathologist and deep learning segmentation across all structures (glomerular tuft, proximal tubules, distal tubular segments, peritubular capillaries, and arteries and arterioles). Although machine learning will never replace the experience of a histopathologists, large-scale evaluation especially of quantitative changes of specific structures will be possible in adults and children with (genetic and nongenetic) FSGS and may help to identify prognostic factors [61].

Research Directions of Histopathology

MCD and FSGS have historically been viewed as one entity, as progression from apparent MCD to FSGS occurs in some patients; also in some patients with FSGS, treatment can induce sustained remission, even after discontinuation, suggesting that FSGS can regress in MCD [62]. It is also known that there is complex interaction between resident cells of the glomerulus leading to FSGS (Table 1).

However, detailed immunostaining, morphometry, and even proteomic studies reveal differences in the biopsies of those patients without diagnostic segmental sclerosing lesions even in this presclerotic phase of FSGS versus MCD. These changes include increased expression of markers of activated parietal epithelial cells on the glomerular tuft (e.g., CD44) and marked glomerular hypertrophy. When FSGS recurs in the transplant, evidenced by marked proteinuria developing as early as in the operating room, the earliest structural lesion is only foot process effacement. However, additional studies reveal increased CD44 staining on the tuft, followed by overt sclerosing lesions within weeks [63]. Thus, although foot process effacement is extensive in both MCD and the early presclerotic phase of FSGS, there are important differences even at these earliest stages of podocyte injury. Whether this represents differences in severity of the same injury, or at least in part differing injury mechanisms, remains controversial.

Other changes of parietal epithelial cell phenotypes – even in unaffected glomeruli – have been demonstrated. In the collapsing variant, normal-appearing glomeruli had more claudin and CD44 positive cells and less WT1 in tuft area compared to controls. In contrast, more WT1 was found in tip lesions. A recent study demonstrated that glomerular epithelial lesions can be formed not only from the classical flat but also from proximal tubular epithelial cells: intermediate (located at the tubular orifice) and cuboidal PECs [64]. In mice, these cells expressed activation markers (CD44 and KI-67) and formed sclerotic lesions. Patients with FSGS and tip lesions expressed markers of intermediate PEC, which can be explained by the localization of these cells at the tubular pole. In summary, epithelial cells may not only contribute to the formation of sclerotic lesion but also to the colonization of unaffected glomeruli thus promoting lesion formation. Staining for parietal epithelial markers, such as PAX8, may also become a tool in diagnostic histopathology [65].

The formation of extracellular matrix is the final event. Increased numbers of pro-fibrotic molecules such as angiotensin, its pro-fibrotic AT1 receptor, TGF-ß, and various others have been demonstrated in FSGS. A recent study used proteomics to study the extracellular matrix composition in human biopsies in collapsing and classical FSGS [66]. Extracellular matrix proteins were more abundant in the collapsing than in the classical variant, especially transcripts of cathepsin B, C, and annexin. Interestingly, expression markers of epithelial cells but not of podocytes were demonstrated, again underlining the important role of parietal cells, also as a possible therapeutic target.

Taken together, histopathology not only plays a major role in the diagnosis (or exclusion) of

Table 1 Resident cells of the glomerulus and FSGS

Resident cell type	Role in pathogenesis
Glomerular endothelial cell	Endothelial cell-podocyte cross talk: Glomerular endothelial mitochondrial oxidative stress and dysfunction leads to podocyte loss
Parietal epithelial cell	Activation leading to hypertrophy, hyperplasia, and migration from Bowman space to the glomerular tuft, with subsequent increased production of extracellular matrix
Visceral epithelial cell (podocyte)	Disruption of cell cytoskeleton causes effacement leading to loss of integrity of foot processes and slit diaphragm
Mesangial cell	Injury and hypercellularity often found but unclear if primary or secondary mechanism

FSGS but also is a strong instrument to clarify distinct pathogenetic mechanisms of podocyte dysregulation leading to extracellular matrix formation; ultimately, this will also open the window for more effective treatment.

Management

The management of patients with SRNS is challenging because of variable response to immunosuppression, therapy- and disease-related adverse effects, risk of progression to chronic kidney failure, and likelihood of posttransplant recurrence. With any immunosuppressive strategy, the intent is to induce complete remission of proteinuria (protein/creatinine ration <0.2 mg/mg), which is associated with favorable long-term outcomes [67]. However, also achievement of a partial remission has been shown to improve prognosis [68]. This is often defined as proteinuria of >0.2–2 mg/mg creatinine or cessation of edema and increase of serum albumin >25 g/l. A suggested definition of nonresponse is persistence of proteinuria >2.0 or presence of edema with serum-albumin <25 g/l [69].

Based on limited information from clinical trials examining the efficacy of immunosuppression in inducing and maintaining remission, the current standard of care for childhood SRNS comprises of a combination of treatment approaches, including calcineurin inhibitors, alternate day prednisone, and adjunctive measures such as RAAS blockade [70]. It should be emphasized, however, that in the past, no prospective study has differentiated between idiopathic steroid-resistant nephrotic syndrome and genetic forms. Patients with genetic forms (including those with APOL1 risk variants) have an inferior response to immunosuppression and testing has not been performed even in some recent controlled studies. Therefore, previous studies should be interpreted with some caution. In addition, publication bias and geographical differences reflecting differences in genetic background have to be taken into account, since they might have an impact on treatment response. A suggested management algorithm is presented in Fig. 3.

Immunosuppressive Regimens

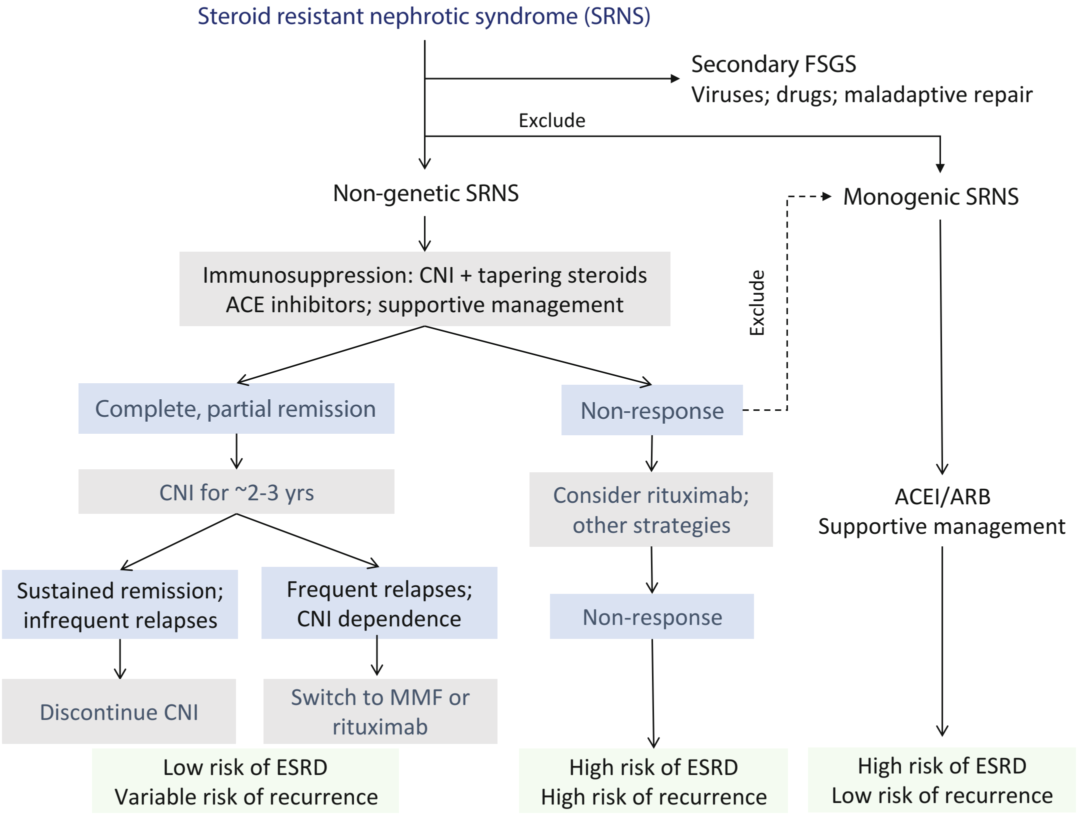
Pulse Corticosteroids

In view of the poor prognosis in the pre-CNI era, early studies had examined the utility of IV methylprednisolone (20–30 mg/kg for 6 alternate days; then weekly for 8 doses, fortnightly for 4 doses, monthly for 8 doses, and bimonthly for 4 doses) or IV dexamethasone (4–5 mg/kg for 6 alternate days, then fortnightly for 4 doses, and monthly for 8 doses), usually along with oral cyclophosphamide [71, 72]. While complete or partial remission were observed in 30–50% cases, high risk of steroid toxicity (hypertension, hypokalemia, hyperglycemia, steroid psychosis) and systemic infections are reasons why these are no longer recommended in management of steroid resistance [73]. Recently, however, combination of a calcineurin inhibitor with pulse methylprednisolone was able to achieve sustained remission in 84% of children in a single center study so that this approach might be an alternative for individual refractory patients [74].

Calcineurin Inhibitors (CNI)

Calcineurin inhibitors suppresses IL2-mediated T-cell activation and have been used in the treatment of nephrotic syndrome since the mid-1980s. In addition to its immunosuppressive action, cyclosporine has been found to have a direct hemodynamic effect and is able to stabilize the actin-cytoskeleton of podocytes; these two effects may be the explanation for its effect in non-immunologic, genetic SRNS [75].

Calcineurin inhibitors along with alternate day steroids are currently viewed as the first-line treatment of SRNS. Information from 9 RCTs examining the efficacy of cyclosporine or tacrolimus for SRNS indicates that these agents induce remission in up to 70% cases (250 patients; 95% CI 64.1–75.3%), which is more than reported for other therapies. Meta-analysis indicates that use of either CNI is associated with higher likelihood of remission at 6–12 months versus no treatment (2 RCT; RR 3.5; 95% CI 1.0–9.6) or therapy with IV cyclophosphamide (3 RCT; RR 1.98; 95% CI 1.25–3.13) [5]. Cyclosporine and tacrolimus have similar efficacy (2 RCT; RR 1.1; 95% CI 0.9–1.3)



Steroid resistant nephrotic syndrome (SRNS)
Secondary FSGS
Viruses; drugs; maladaptive repair
Exclude
Non-genetic SRNS
Monogenic SRNS
Immunosuppression: CNI + tapering steroids
ACE inhibitors; supportive management
Exclude
Complete, partial remission
Non-response
CNI for ~2-3 yrs
Consider rituximab; other strategies
ACEI/ARB
Supportive management
Sustained remission; infrequent relapses
Frequent relapses; CNI dependence
Non-response
Discontinue CNI
Switch to MMF or rituximab
Low risk of ESRD
Variable risk of recurrence
High risk of ESRD
High risk of recurrence
High risk of ESRD
Low risk of recurrence

Fig. 3 Outline of principles of management in pediatric patients with idiopathic steroid-resistant nephrotic syndrome (SRNS)

and comparable risk of nephrotoxicity or hypertension [70]. Data collated in disease registries report lower rates of remission (41–76% patients), possibly due to selection bias, attrition, and confounding [67, 76].

Both the IPNA and KDIGO guidelines recommend first-line use of CNI for patients with SRNS [6, 8, 77]. Cyclosporine and tacrolimus are available options and seem to be equally effective [78]. Selection of either treatment partly depends on local preference and experience as well as consideration of side effects. While tacrolimus lacks the cosmetic adverse effects, cyclosporine may be preferred in patients with seizures or at-risk of diabetes. Dose titration is essential with either agent since bioavailability is variable and therapeutic index narrow; under- and overdosing might lead to nonresponse and toxicity, respectively. Therefore, close pharmacokinetic monitoring should be employed, typically aiming at trough levels of 80–150 ng/mL for cyclosporine and 4–8 ng/mL for tacrolimus.

The median time to remission is 2–4 months [70]; patients with nonresponse despite therapy with CNI in adequate doses for 6 months can be considered for other immunosuppressive strategies including discontinuation of CNI [73], unless they have achieved partial remission. It should be noted, however, that individual patients achieve complete remission only after years [62]. Patients in sustained remission for more than 6 months may be managed on lower doses [79]. Therapy should be withheld during episodes of acute kidney injury (AKI) or in patients with persistently low eGFR.

The optimal duration of treatment with CNI for patients who achieve partial or complete remission is not determined. In view of the poor prognosis of SRNS, evidence-based guidelines usually recommend therapy for 1 year or longer [73, 80]. Most patients would be continued on a CNI for 2–3 years or even longer before attempting withdrawal. In one study, discontinuing CNI has been shown to be feasible in the majority of patients in sustained remission [62], but may risk relapse. Other weaning protocols have been used, e.g., with MMF [81] or rituximab [82]; however, no randomized controlled studies are available. On the other hand, long-term CNI therapy beyond carries a risk of irreversible chronic nephrotoxicity, characterized by striped pattern of tubule-interstitial fibrosis and peripheral arteriolar nodular hyalinosis [11]. Risk factors for histological nephrotoxicity, observed in 10–25% cases treated for 2 years or longer, include high CNI dose, persistent heavy proteinuria, and hypertension [83, 84].

Patients who attain remission with CNI but continue to experience disease relapses despite adequate trough levels are considered for switch to alternative therapies. Retrospective studies indicate successful switch from therapy with cyclosporine or tacrolimus to mycophenolic acid, usually mycophenolate mofetil (MMF) or rituximab (discussed below). However, a recent randomized controlled trial found continued therapy with tacrolimus twice as effective in maintaining remission compared to switch to MMF after 6 months (90% vs. 45%) [85].

Mycophenolate Mofetil (MMF)

MMF is the prodrug of mycophenolic acid (MPA), an inosine monophosphate dehydrogenase inhibitor that interferes with de novo purine biosynthesis in proliferating B and T-lymphocytes. It also inhibits lymphocyte recruitment, myofibroblast infiltration, mesangial proliferation, and podocyte apoptosis. Given its lack of renal, hemodynamic, and metabolic adverse effects, MMF was tested as a safe alternative to CNI. However, contrary to the efficacy of MMF in patients with frequently relapsing steroid-sensitive disease, response is less satisfactory in patients with SRNS [86].

MMF was used in pediatric patients with SRNS in 9 prospective and retrospective case series, as summarized recently. Therapy with MMF induced complete or partial remission in 56 (62.2%) of 90 patients included in 4 studies. In 5 additional studies including 35 patients with CNI-dependent disease, MMF sustained remission when CNI was discontinued [87]. However, remission was sustained in only 17% cases treated with MMF in the PODONET cohort [67]. In the NIH-funded multicenter open label FSGS Clinical Trial, complete or partial remission was observed in 22 (33.3%) of 66 patients receiving MMF oral pulse dexamethasone, as compared to 33 (45.8%) of 72 randomized to receive cyclosporine [88]. A single-center RCT found lower remission rate in patients switched to MMF after 6 months of therapy with tacrolimus, compared to those continued on tacrolimus (44.8% vs. 90.3%) [85].

One lacuna in past studies was the lack of attention to therapeutic drug monitoring. An area under the curve >45–60 μg*h/mL is shown to be an important determinant of response to MMF in patients with steroid-sensitive nephrotic syndrome [89]. Future studies examining the efficacy of MMF in inducing remission of SRNS or in maintaining CNI-induced remission of proteinuria should ensure targeting adequate MPA levels. Therapy with MMF is useful in maintaining remission in patients with CNI-dependence and/or features of toxicity. Close monitoring for adverse effects, including gastrointestinal disturbances and myelosuppression, is necessary, particularly at high doses (▶ Table 3, Chap. 14, “Steroid-Sensitive Nephrotic Syndrome”) [90].

Rituximab

In the last two decades, rituximab has emerged as an effective strategy for sustaining remission in patients with steroid- and calcineurin inhibitor (CNI)-dependent nephrotic syndrome [69, 91]. Binding of this monoclonal antibody to CD20 on the B lymphocyte surface induces apoptosis and B-cell depletion, which might alter T-cell function and restore the balance between T-regulatory and Th17 cells [92]. The agent is also postulated to act directly on podocytes by upregulating sphingomyelin phosphodiesterase activity to stabilize the actin cytoskeleton [93].

In their first report in 2007, Bagga et al. reported an excellent response to rituximab in all five treated patients, including three with FSGS. Three patients achieved complete remission, and two partial remission [94]. Further studies indicated, however, that rituximab appears to have limited efficacy in inducing remission in patients with CNI-refractory SRNS as compared to steroid-sensitive nephrotic syndrome [95]; no response was seen in 70.7% of patients with SRNS, and there was a higher proportion with MCD that showed remission compared with FSGS [96]. A randomized controlled trial on 31 children with CNI-refractory SRNS showed no reduction of proteinuria at 3 months and 6 months following addition of rituximab to therapy with steroids and CNI. However, a remission of proteinuria was noted in six patients with delayed resistance (i.e., patients with secondary steroid resistance), indicating that this subgroup may respond differently [97].

In a multicenter open label single-arm trial, 9 (39.1%) of 23 patients with CNI-refractory SRNS achieved remission within 6 months of treatment with rituximab [98]. A review of therapy with rituximab in 234 pediatric patients with refractory SRNS (13 case reports, 10 case series) showed remission in 50.4% (range 18.8–80%) patients, including complete remission in 29.8% and partial remission in 22.9% cases [99]. A systematic review, including 226 patients with CNI-refractory SRNS (7 case series and 1 RCT), reported remission in 46.4% cases [100]. Further, these reviews indicated a trend to higher rates of response to rituximab for patients with minimal change versus FSGS, and for those with late versus initial resistance; patients with partial remission also seemed to have a better response to rituximab in a retrospective analysis Mason [101]. However, remission rates in uncontrolled studies might have been overestimated due to the inclusion of an admixture of CNI-dependent and CNI-resistant patients, effect of concomitant immunosuppression, and short follow-up.

Despite limitations, many pediatric nephrology centers use intravenous rituximab in selected patients of steroid- and calcineurin inhibitor-resistant nephrotic syndrome. The dose and frequency of administration is not defined. A range of doses from 375 mg/m^2 (single, or up to four doses) to 750 mg/m^2 per dose (two doses given 7–14 days apart) have been used. No head-to-head studies comparing different dosing schedules have been performed in SRNS (in contrast, e.g., compared to steroid-sensitive nephrotic syndrome, where a difference between intensive and moderate dosing schedules did not show a difference in response rates.) The pharmacokinetics of rituximab are altered in proteinuric patients; enhanced drug clearance leads to reduced area under the curve and shorter half-life, justifying considerations for higher doses and frequent redosing [102]. While some authors monitor B-cell depletion in order to decide on re-treatment, others have shown that monitoring of memory B-cells may be more important, since not all patients with B-cell recovery relapse [103].

Therapy with rituximab appears to be more useful when it is used to maintain remission of CNI-dependent disease, especially in patients with prolonged CNI use or its toxicity. Studies report high rates of complete or partial remission, reduced immunosuppressive drug requirement, and/or improvement in eGFR in patients treated with rituximab [99]. However, B-cell repopulation is followed by recurrence of relapses, leading to consideration of additional immunosuppression (e.g., with MMF) [96] or repeated doses of rituximab, either following relapses or upon B-cell repopulation as strategies to sustain remission. Given concerns regarding adverse events, the optimal dosing strategy remains unclear.

In an interesting small series by Basu et al., 10 out of 15 patients achieved complete and 5 achieved partial remission in SRNS patients when MMF was given after an initial lack of response to RTX; most patients had MCD [104]. Whether this protocol increases remission rates after RTX needs to be confirmed by future studies, however. Kamei et al. treated 10 patients with SRNS who were unresponsive to CNIs with RTX and pulse steroids and was able to achieve remission in 6 children [105]. Although this approach needs to be confirmed by a prospective, controlled study, it may be that a combination of RTX with other immunosuppressants (MMF, steroids or others) may be successful in some patients with SRNS.

Ofatumumab

This fully humanized anti-CD20 monoclonal antibody induced remission in anecdotal cases of CNI-

and rituximab-refractory SRNS and rituximab- and plasmapheresis-refractory posttransplant recurrent FSGS. Basu administered ofatumumab to two patients with MCD and three patients with FSGS [106]. All received multiple medications before this intervention, including two courses of RTX. After ofatumumab, improvement of proteinuria and an increase in the serum albumin levels from 1.2 g/dl to 3.1 g/dl within 6 weeks was noted. Hypoalbuminemia resolved after the third dose and remission was achieved after six doses. No serious side effects were reported [106]. However, a subsequent placebo-controlled RCT was terminated prematurely for futility after none of 13 patients with steroid- and CNI-refractory SRNS administered one dose of ofatumumab (1500 mg/1.73 m^2 IV) showed response [107]. Ofatumumab, however, may be an alternative antiCD20 agent in patients with intolerance reactions to rituximab.

Cyclophosphamide

Cyclophosphamide is an alkylating agent acting on B- and T-cells; while it has been widely used in steroid-sensitive nephrotic syndrome results in SRNS did not show a benefit when compared to oral steroids alone [70, 108]; therefore, oral cyclophosphamide is no longer recommended for management of SRNS.

Intravenous cyclophosphamide has been shown to be more effective that oral administration in in two Indian studies; rates of complete remission were 14.8–29.2% of patients [109, 110]. Another RCT comparing IV to oral cyclophosphamide in 50 children showed early remission (60% vs. 52%) followed by disease relapses in the majority; adverse effects were common (36% vs. 20%) [111]. Comparing intravenous cyclophosphamide to CNI, results of two multicenter RCTs indicate that therapy with IV cyclophosphamide is associated with significantly lower rates of remission than CNI (RR 0.5; 95% CI 0.4–0.7) [70]. One study showed that therapy with cyclosporine (150 mg/m^2/day) versus IV cyclophosphamide (500 mg/m^2 q monthly for 7 doses) was associated with remission in 9 of 15 (60%) versus 3 of 15 (20%) at 6 months [112]. Another study of 131 patients, found 6-month complete and partial remission rate of 45.9% with IV cyclophosphamide and 82.5% with tacrolimus; the rate of complete remission was 14.8% and 52.4%, respectively [110]. Given the unsatisfactory response to therapy with IV cyclophosphamide, the use of this medication is considered only in patients with contraindication to CNI, and in regions where CNI are not available.

Combination of Immunosuppressive Agents

As treatment-resistant FSGS carries a high risk of progression into ESKF, attempts to achieve remission with other biological drugs and interventions are important. Every single patient achieving complete remission should be viewed a success. If no response with a single-drug approach cannot be achieved, combination of different drugs may be an option. For instance, information on 49 patients (4 case series) with CNI-refractory or CNI-dependent SRNS, summarized in a recent review, indicate that therapy with the combination of CNI and MMF might enable remission in 33 (67.3%) patients with CNI-refractory disease, without major adverse events [87]. Multi-therapy with rituximab, IV methylprednisolone pulses, and cyclosporine or MMF was associated with complete remission in six patients with CNI-refractory SRNS; however, redosing was associated with hypogammaglobulinemia [113]. Controlled studies with vigilance for infections should evaluate the safety and efficacy of strategies involving intense immunosuppression.

Novel Therapeutic Strategies

These include immunosuppressive and non-immunosuppressive approaches. Regarding immunosuppressive treatment, several agents have been studied in SRNS.

Anti-IL 2 Antibodies

In a pilot case–control study with five patients who were resistant to all available treatments, including RTX, Bonanni et al. administered anti-IL 2 antibodies, because IL2 blockade increases Treg lymphocytes; in experimental models, upregulation of Treg immunity improves nephrotic syndrome. Unfortunately, in their study, Bonanni did not ameliorate proteinuria, and in all five children, kidney disease had progressed after 2 years [114].

Abatacept

This fusion protein of cytotoxic T-lymphocyte-associated protein 4 (CTLA-4) and immunoglobulin blocks the CD28:CD80/CD86 interaction, thus blunting the costimulatory signal for T-cell activation. Yu et al. demonstrated CD80 (B7-1) overexpression in podocytes in biopsies in primary and recurrent FSGS as well as remission of proteinuria in five patients with CNI-refractory SRNS or posttransplantation recurrence treated with abatacept (given at 10 mg/kg IV once, repeated every 15–30 days, if required and tolerated) [115]. However, subsequent studies have contested the findings of CD80 expression on podocytes as well as the efficacy of abatacept in inducing remission [116]. Currently, a new trial investigation of the role of abatacept is under way implementing a precision medicine-based approach [117].

Adalimumab

This monoclonal antibody that blocks tumor necrosis factor (TNF)-α was associated with partial remission in four out of ten patients with primary FSGS in the FONT-I study, a phase I trial [86]. However, none of seven patients randomized to receive adalimumab (at 24 mg/m^2 administered subcutaneously biweekly for 16 weeks) exhibited remission at 6 months in the FONT-II trial [118].

Fresolimumab

This monoclonal antibody targets transforming growth factor-β (TGF-β), overproduction of which is implicated in the pathogenesis of fibrosis in FSGS. While a phase I trial reported complete or partial remission in 3 of 16 adults with primary FSGS administered one IV dose at 1 mg/kg [86], none of the 26 patients randomized to receive a dose of fresolimumab (at 1 mg/kg or 4 mg/kg) in the subsequent phase II trial achieved remission, leading to trial closure for futility [119].

Adrenocorticotropic Hormone (ACTH)

While ACTH was replaced by prednisone as the primary therapy for nephrotic syndrome in 1960s, interest in this synthetic hormone was revived by uncontrolled studies demonstrating significant reduction in proteinuria in adult patients with glomerulonephritis treated with ACTH gel (80 U/1.73 m^2 twice weekly) or intramuscular administration of its analogue tetracosactide (1 mg weekly for 1 year) [120]. A prospective pilot study of 24 patients using the same dosing strategy reported full remission in 2 and partial remission in 5 of 15 adults with steroid-resistant FSGS [121]. The multicenter ATLANTIS RCT that randomized children with frequently relapsing steroid-sensitive disease to receive therapy with ACTH (80 U/1.73 m^2 twice weekly) for 6 months versus standard therapy, was terminated prematurely for futility after interim analysis in 31 patients [122]. ACTH is still promoted by some authors [123]; in experimental models, ACTH seems to be able to support podocyte recovery [124].

Non-immunosuppressive Strategies

Other recent studies also evaluated non-immunosuppressive interventions to treat SRNS.

Low-Density Lipoprotein (LDL) Apheresis

Lowering of lipid levels might improve macrophage function, reduce endothelial dysfunction, prevent direct lipotoxicity to the glomeruli, improve renal blood flow, and reduce inflammation. Information on LDL apheresis in 47 patients (17 children) with SRNS, including CNI-refractory and recurrent FSGS, was summarized recently [125]. Apheresis was performed using Liposorber® LA-15 or LA-40 filters (Kaneka Pharma America LLC), based on dextran sulfate cellulose adsorption, for median 12 (range 4–24) sessions over 9 (2–52) weeks, with or without concomitant use of steroids, cyclosporine, and/or statins. Complete and partial remission were reported in 19 (40.4%) and 14 (29.8%) patients, respectively. However, a prospective multicenter study on 17 patients (15 children) with drug-resistant primary or recurrent FSGS reported remission in only 2 of 4 patients at 3 months and 2 of 3 patients at 6 months after therapy

[126]. Apheresis carries risk of complications similar to other extracorporeal therapies, and the equipment is not marketed in several regions. In another pediatric study, seven patients with recurrence after transplantation were treated with steroids and LDL-A and all showed reduction of proteinuria or complete remission and demonstrated improvement in their GFR [127]. Taken together, LDL-apheresis might proof to be a valuable rescue treatment, although publication bias may be present; more studies are warranted.

Galactose

Anecdotal reports suggested that oral galactose binds to the serum "circulating" factor to inhibit its activity and reduce proteinuria in individual patients with refractory FSGS [9, 11, 128]. However, a subsequent trial of oral galactose (0.2 g/kg twice daily, max. 30 g daily) found no reduction in proteinuria in seven pediatric patients with SRNS, although glomerular permeability assay showed an improvement [129]. A phase II clinical trial reported partial remission in 2 of 7 patients with FSGS at 6 months of therapy with oral galactose [118]. Although the authors concluded that further studies using galactose should be performed and, for example, patients with earlier disease stages should be treated. Practical difficulties in using galactose include the need to ingest large oral doses and lack of ready availability.

Sparsentan

This is a dual-acting angiotensin receptor blocker (ARB) and highly selective endothelin type A receptor antagonist. A phase II blinded RCT (DUET) compared reduction in proteinuria following therapy with oral sparsentan (200 mg, 400 mg, or 800 mg, once daily) to oral irbesartan (300 mg, once daily) in patients with primary FSGS [130]. Therapy with sparsentan showed greater reduction in proteinuria (45% vs. 19%) and a higher (28% vs. 9%) proportion of patients achieved the partial remission end point (spot urine protein to creatinine ratio ≤ 1.5 g/g and $>40\%$ reduction from baseline) without significant adverse effects [130]. While results of another RCT (DUPLEX) are awaited, the agent appears promising as adjunctive therapy in SRNS.

Adjunctive Therapies

Prednisone on alternate days and RAAS inhibitors usually accompany all immunosuppressive strategies. Prednisone is initially given at 30–40 mg/m^2 (1–1.5 mg/kg) on alternate days and tapered to discontinue therapy 6–9 months later in those that enter remission [69]. Disease relapses are common, and usually steroid-sensitive; compliance and adequacy of therapy with CNI must be ensued in patients with frequent relapses.

Therapy with RAAS blockers (ACEI or ARB) is recommended for all patients with SRNS since it is associated with dose-dependent reduction in proteinuria, known to retard CKD progression via the TGF-ß pathway. It has been used in combination with indomethacin (chemical nephrectomy, especially in genetic forms of SRNS) [75]. Therapy is withheld in presence of hypovolemia and/or AKI. The potential future role of sparsentan, a dual-acting ARB and highly selective endothelin type A receptor antagonist that was shown to achieve greater reduction of proteinuria than irbesartan has been mentioned.

Supportive Care and Management of Complications

Principles of management of complications and components of supportive care will be covered elsewhere (see ▶ Chap. 14, "Steroid-Sensitive Nephrotic Syndrome").

Outcomes

Information on disease activity in SRNS on the long term is limited. Outcomes on medium-term range from sustained remission after CNI are discontinued, to a relapsing illness that requires switch to less toxic regimens [62, 79]. Pooled data from five large multicenter collaborative studies including 1107 patients with SRNS indicates complete remission in 26.7% [95% CI 24.2–29.4%] cases, partial remission in 18.4% [16.2–20.8%] cases, and nonresponse in 54.8% [51.9–57.7%] patients [67, 76, 101, 131], Table 2. The lower rates of remission as compared to randomized

studies might reflect medium-term outcomes and real-world effectiveness of immunosuppressive therapies; however, large databases often lack accurate phenotyping and are limited by selection and information bias, risk of attrition, and confounding.

Multicenter observational cohorts demonstrate that etiology of disease and response to immunosuppression are the chief determinants of long-term outcome. Based on information from four studies, the odds ratio for nonresponse in patients with genetic versus nongenetic disease is estimated at 4.0 [95% CI 2.5, 6.5; $P < 0.0001$] and that of kidney failure at 2.9 [2.2, 3.7; <0.0001] [67, 76, 101, 132]. Among patients with undifferentiated or nongenetic SRNS, response to immunosuppression predicts kidney survival, with significantly higher risk of kidney failure in patients with persistent nonresponse. Pooling data from 5 cohorts, the rates of survival free of kidney failure at 10-year follow-up are estimated at 92.9% [95% CI 85.8–97.7%] in patients with complete remission, 72.6% [64.8–79.8%] in patients with partial remission, and 35.1% [22.2–49.3%] in patients with nonresponse [67, 76, 101, 131, 132].

Renal histology and type of steroid resistance might also impact outcomes. Patients with minimal change disease demonstrate higher rates of remission and better prognosis than those with FSGS [70]. Patients with FSGS tip lesion tend to have a favorable outcome, while collapsing glomerulopathy has the lowest remission rate and high risk of progression to kidney failure (see above). Information from large case series indicates that the majority of patients with late steroid resistance show minimal change disease on biopsy, usually respond satisfactorily to immunosuppression, and rarely progress to kidney failure. Secondary steroid-resistant patients had significantly higher complete response than those with genetic-testing-negative primary steroid resistance (43% vs. 23%; $P = 0.001$) [101]. However, data collated from RCTs indicates similar response to immunosuppression for patients with initial or late steroid resistance [70].

Overall, response to immunosuppression appears to be the most important determinant of long-term outcome in SRNS. Patients who continue to have disease relapses, persistent proteinuria or decline in renal function into adulthood require transition into care by “adult” nephrologists.

Transplantation

FSGS ranks third among the causes of kidney failure or transplantation in regional pediatric dialysis and transplant registries, accounting for 10–12% cases [in the North American Pediatric

Renal Trials and Collaborative Studies, Latin American Registry of pediatric renal transplantation and UK Renal registry]. Disease recurrence after transplantation, presumably secondary to the “circulating factor,” has been observed in the immediate posttransplantation period in 30–50% cases in retrospective series and is an important determinant of outcomes. Recent data from the NAPRTCS suggests a lower rate of 5-year allograft survival in patients with FSGS compared to other etiologies (74% vs. 87%) [133].

The rate of recurrence appears to be unchanged in the decades following changes in posttransplant immunosuppressive regimens. Summation of data from 5 recent large multicenter reports, including the UK National Registry of Rare Kidney Diseases [101], PodoNet registry [67], France [134], Italy [135], and the United States [133], indicates disease recurrence in 218 of 682 pediatric kidney allograft recipients, implying a recurrence rate of 32.0% (95% CI 28.6%, 35.6%). Recurrent FSGS is associated with allograft loss in 50–60% of cases that do not respond to changes in immunosuppression and therapeutic apheresis. Strategies targeting early detection and aggressive management of recurrent FSGS have improved outcomes to enable partial or complete remission of proteinuria in 60–75% cases [136]. Disease recurrence in the first allograft confers very high (>80%) risk of recurrence in subsequent allografts.

The chief risk factor for recurrence appears to be a diagnosis of nongenetic disease, reflected in difference in recurrence rates between patients with genetic versus nongenetic disease (<5% vs. 28–68% cases, respectively). Posttransplant proteinuria, affecting approximately 30% of patients with homozygous Fin-major mutations in *NPHS1*, is caused by a de novo glomerulopathy associated with the generation of anti-nephrin antibodies in response to the allograft nephrin, which represents an immunologically foreign molecule in patients lacking nephrin expression [137]. Despite anecdotal reports of recurrent disease in patients with *NPHS2* variations, the overall risk of posttransplant recurrence is low, similar to other forms of genetic SRNS that almost never recur.

Historically, the majority of patients with genetic disease might have been undiagnosed, due to lack of access to genetic testing and limited number of genes screened. Plausibly, the difference in risk of disease recurrence reported for patients with late (initial steroid sensitivity) versus initial steroid resistance (93% vs. 30%; odds ratio 30; 95% CI 6.6–135.9) [136] reflects the difference between nongenetic and genetic SRNS. Similarly, recurrence is more common in patients with native kidney biopsy finding of MCD versus FSGS (75% vs. 40%; adjusted odds ratio 5.6; 95% CI 1.3–23.7), and in older versus younger children (threshold age 6–9 years), categories that likely reflect the clinical phenotypes of initial steroid sensitivity (nongenetic disease) and genetic SRNS, respectively. However, the relationship with age is not definite; another study suggests higher risk in younger children. Other inconsistent risk factors are rapid progression to kidney failure (<3 years from disease onset), mesangial proliferation on native kidney biopsy, native kidney nephrectomy, Caucasian race, and living related (versus deceased) donor transplantation or HLA-AB match.

Evaluation for posttransplant recurrence of SRNS, and its management including preemptive approaches, is discussed elsewhere (see ▶ Chap. 82, “Recurrent Disease After Pediatric Kidney Transplantation”). Briefly, recent clinical practice recommendations advise attention to specific recipient and donor factors during that pretransplant evaluation.

Abstract

Membranous nephropathy is a glomerular disease that mainly affects adults. In children, it can present starting from the first days of life, though it is more frequent in adolescents and young adults. Among glomerular disorders, it stands out as a disease whose pathogenesis in the last decade has been elucidated with the discovery of the driving antigen in the majority of cases, leading to the potential for simplified diagnosis and tailored therapeutic approaches. This chapter presents an overview on the different forms of membranous nephropathy that can affect children and on the advances in diagnosis and treatment that have been made in this exciting field.

Keywords

Introduction

Membranous nephropathy (MN) is histologically defined by the presence of deposits of immune complexes located on the outer aspect of the glomerular basement membrane (GBM). These deposits are electron dense by electron microscopy. By immunofluorescence (IF), they contain immunoglobulins G (IgG), the relevant antigens that have long eluded identification, and the membrane attack complex (MAC) of complement, thought to be the mediator of proteinuria. MN is the major cause of nephrotic syndrome (NS) in adults. In children, it is a rare disease and its diagnosis is currently made on a biopsy indicated because the atypical clinical presentation and/or outcome under steroid therapy does not fit with the diagnosis of minimal change disease, which is the most common cause of NS in this age range [76]. Clinical manifestations of MN include proteinuria, hematuria, overt NS, and in some cases kidney dysfunction.

There are few diseases in nephrology where pathophysiological advances have been as rapid and have had such a major impact on patient care as MN. At the time of writing this chapter, most antigens implicated in MN have been identified. It is remarkable that the first podocyte antigen ever identified in humans was neutral endopeptidase (NEP) in a rare subset of children with antenatal MN [24]. This discovery provided the proof of concept that in humans, the disease mechanism closely resembles the rat experimental model of Heymann nephritis [48] and paved the way for identification of the major antigen, PLA2R, in adult MN [5]. Pediatric cases also provided the first examples of food-induced MN caused by cationic bovine serum albumin [26]. Since then, additional antigens have been identified, providing clues to the etiology and invaluable tools for patient monitoring. We now know that these antigens are age-dependent, i.e., each antigen has a specific prevalence according to age. Identification of these antigens has reduced the number of “idiopathic” cases of MN and elucidated the link between certain diseases (cancer, SLE) and MN.

We have entered an era of therapeutic progress where biotherapies have a growing role. In adult MN, rituximab is now head-to-head with cyclophosphamide as first line of treatment in patients with MN and persisting NS [93]. Other agents modulating B cells, plasma cells, and complement are knocking at the door, and combination therapies should also be considered.

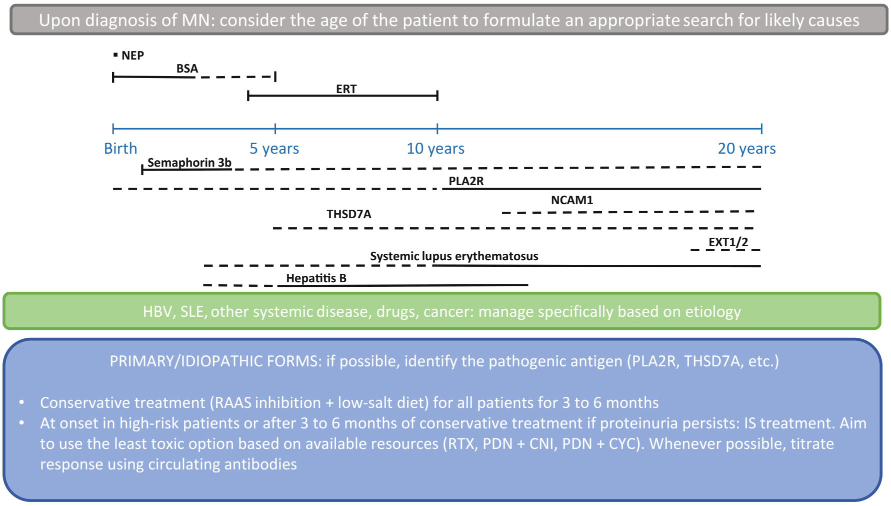
Incidence, Prevalence, and Etiology

MN in children is an infrequent histological diagnosis, especially compared to adults. Historically, while in adults its incidence was found to be 1.2/100.000/year, in children it was 0.1/100.000/year. However, its frequency as the underlying cause of NS steadily increases with age from about 1–2% at ages 1–5 years to about 5% at 10 years, about 10% at 15 years and roughly 18–22% at 18–20 years of age. As children with steroid-sensitive forms of NS are not routinely biopsied, some patients with forms of MN that respond to glucocorticoids may fail to be recognized.

In terms of gender, while in adults primary MN is more frequent in males compared to females, in children, the frequency is very similar between genders [76]. Chen et al. found a 6:7 male to female ratio in a US cohort of pediatric MN [16], and Liu et al. found 23 male and 21 female MN patients in a Chinese pediatric cohort [55]. Another study reports that MN was more frequently diagnosed in girls.

The etiology of MN varies with age. Figure 1 shows the most probable forms of MN at different ages.

In children <1–2 years of age, though exceptional, MN can be due to circulating antibodies of alloimmune origin, auto-antibodies to the phospholipase A2 receptor (PLA2R) transmitted by a mother with immunologically active MN [75], or semaphorin 3B [79]. In the congenital form, the mother carries a homozygous mutation in the *MME* gene (3q25.2) coding for neutral endopeptidase (NEP), a protein expressed on podocytes. Maternal antibodies against NEP are formed during pregnancy and pass the placental barrier during fetal life, leading to the presence in the offspring of MN due to alloimmunization with maternal antibodies [24]. Another early-onset



Upon diagnosis of MN: consider the age of the patient to formulate an appropriate search for likely causes

HBV, SLE, other systemic disease, drugs, cancer: manage specifically based on etiology

PRIMARY/IDIOPATHIC FORMS: if possible, identify the pathogenic antigen (PLA2R, THSD7A, etc.)

- Conservative treatment (RAAS inhibition + low-salt diet) for all patients for 3 to 6 months
- At onset in high-risk patients or after 3 to 6 months of conservative treatment if proteinuria persists: IS treatment. Aim to use the least toxic option based on available resources (RTX, PDN + CNI, PDN + CYC). Whenever possible, titrate response using circulating antibodies

Fig. 1 Suggested management of MN in childhood. Upon diagnosis of MN in child, usually by kidney biopsy but potentially in older children/adolescents by identification of positive anti-PLA2R circulating antibodies, a logical step-wise approach should be followed. First, based on the age of the child, the most likely causes must be identified (see text for details). Briefly, in neonates, the congenital NEP form must be suspected; in infants, the cBSA form; in children aged 1–3, the semaphorin 3B form; in children with a metabolic disease on recombinant human arylsulfatase B or alpha-glucosidase, the enzyme replacement therapy (ERT) form; in children living in HBV endemic areas particularly aged 5–7, HBV form; and in children > age 10–12, either SLE or primary forms driven by one of the known antigens, particularly PLA2R

form of MN due to an immune reaction, this time directed against a xenoantigen, is caused by IgG antibodies directed against cationic bovine serum albumin (cBSA). It presents in infants and small children (5 months–2.3 years of age in the initial disease description) fed with cow's milk. The subepithelial IgG deposits are immune complexes containing cationic bovine serum albumin [26]. Very recently, a primary form of MN due to anti-semaphorin 3B antibodies has been described, which can present also in children below the age of 2 [79].

In children >2 and below the age of 10–12 years, MN tends to be more frequently secondary. In endemic areas, hepatitis B is most frequently the cause, although many different infectious agents have been associated with. HBV-associated MN by horizontal transmission presents in younger children, usually at 5–7 years of age [11]. Vertical transmission from mother to child is also possible, and in this case, it presents in infancy. The clinical features of HBV-MN are variable; however, nephrotic syndrome is frequently observed, with a very marked (>80%) male predominance. As HBV vaccination becomes universally widespread, the incidence of this form is destined to decrease steeply.

In this age group and in adolescents, SLE is the other major cause of secondary MN. Class V lupus nephritis represents 10–12% of all forms of lupus nephritis in children. Other forms of secondary MN are listed in Table 1. Of note, extremely rare forms of alloimmune MN that can occur in this age group affect children with rare metabolic diseases such as Pompe disease and mucopolysaccharidosis type 6 requiring enzyme replacement therapy (ERT) with alpha-glucosidase and recombinant human arylsulfatase B (rhASB), respectively [27, 44].

Mostly but not exclusively in children aged >10–12 years and in adolescents, MN is due to

Table 1 Secondary forms of membranous nephropathy. (Modified from Valentini Chapter PN7)

Infection	Autoimmune and dysimmune	Drugs	Neoplasia	Alloimmune and other antigens	Other causes
• Hepatitis B in endemic areas • Hepatitis C • Malaria • Syphilis (congenital) • CMV, EBV • Tubercolosis • Bacterial endocarditis (Streptococcus, enterococcus) • Leprosy • Infestations (hydatid cyst, schistosomiasis, filariasis)	• SLE • IPEX • Graves disease, Hashimoto disease • Autoimmune hepatitis • Sarcoidosis • Ulcerative colitis, Crohn's disease, ankylosing spondylitis • Celiac disease • Type 1 diabetes • Sjogren, RA, SS, Mixed connective-tissue disease, dermatomyositis • Pemphigus • Fanconi syndrome due to anti-TBM antibodies • Idiopathic thrombocytopenia	• Gold, mercury • Infliximab, etanercept • Penicillamine • Tiopronin • Captopril • NSAIDs	• Ovarian • Neuroblastoma • Histiocytoma • Wilm's tumour • Gonadoblastoma	• Feto-maternal: MME mutation • Anti-BSA antibodies • Genetic: • ERT in MPS type 6 and Pompe	• De novo post renal Tx • Post BMT • Sickle cell disease • Primary biliary cirrhosis • IgA deficiency

circulating antibodies that recognize antigens expressed on the podocyte, mostly PLAR2 which accounts for the increase in MN prevalence in this age group and rarely THSD7A.

Of note, the incidence of MN is rising steadily in the last 10–15 years. A recent study performed in China shows that between 2004 and 2014, the adjusted odds for MN in adults rose 13% annually over the 11-year period, and that long-term exposure to high levels of pollution, quantified as fine particulate matter <2.5 μ, increased the risk of MN. Within the same study population, a subsequent study focused on children showed a rise in prevalence of MN from 3% of pediatric glomerular diseases in 2004 to 7% in 2014. The reason for this rise is unknown. However, it can be hypothesized that a genetic susceptibility (first hit) combined with a rise in exposure to fine particles due to pollution (second hit) may give rise to the disease. This is most likely not limited to China, as other reports have described a similar increase in India and Pakistan and in Turkey. The steeply declining rates of hepatitis B infection in China, Taiwan, and South Africa, due to national vaccination programs, make it much more likely that the rise in cases of MN is indeed pertaining to primary/idiopathic forms of the disease [76].

Pathophysiology

General Mechanisms

A great deal of our knowledge on the pathogenesis of MN was provided by a model established in 1959 by a pediatrician, Walter Heymann, who immunized rats with extracts of the proximal tubule [40]. This animal model relies on the active immune response of the rat against a brush border antigen and therefore is defined active Heymann nephritis (AHN). It was long hypothesized that the antibodies recognized a cross-reactive antigen present in the blood, thus forming circulating immune complexes that became deposited in the GBM. This hypothesis was contradicted several years later by studies performed in the passive Heymann nephritis (PHN) rat model. In the PHN model, a fraction from the brush border of rat proximal tubules was isolated and injected into sheep to produce antibodies. These antibodies induced MN upon injection to rats. When infused into isolated rat kidney ex vivo, i.e., in the absence of circulating antigen, they were shown to bind podocyte autoantigens thus forming in situ immune complexes that stained positive for IgG, C3, and C5b-9 [20, 88]. Later this antigen was identified by Kerjaschki et al. [47, 48] as the podocyte membrane protein megalin which is identical to the membrane receptor of low-density lipoproteins LRP2 with a MW of about 600 kDa.

Twenty years after megalin/LRP2, the first pathogenic human antigen, an enzyme called neutral endopeptidase (NEP), was identified in 2002 [24] in a case of neonatal MN. NEP is present on the podocytes and the brush border of the renal tubules. The mother had truncating mutations in the *MME* gene, leading to the absence of NEP. Consequently, anti-NEP antibodies were produced during pregnancy and were transferred to her fetus during the last trimester, inducing neonatal MN. Other four families with the same mechanism of disease have been identified [25, 91]. Importantly, production of anti-NEP IgG1 is necessary for the disease to develop, while infants born to mothers producing only IgG4 were not or weakly affected [25, 91]. This is due to the fact that IgG1, not IgG4, activates complement via the classical pathway and inhibit enzyme activity.

Target antigens of circulating antibodies can be classified as intrinsic or extrinsic whether they are produced by the patient or they are provided by external sources (food for instance). The immunopathological characteristics of those antigens and the immune response are described in Table 2. A schematic representation of the pathogenesis of MN is provided in Fig. 2.

Intrinsic Podocyte Antigens

The identification of target antigens in adult MN was unsuccessful for a long time. In 2009, Beck

Table 2 Laboratory investigations and pathology features of MN in children, based on antigen specificity

Podocyte antigen	MN presentation	Age	Serum	Tissue IgG subtype predominance	Unique tissue findings	Prevalence
NEP 1 (intrinsic)	Fetomaternal alloimmune MN	Newborns	Anti-NEP antibodies (in mother and newborn)	IgG1	Staining for NEP within subepithelial deposits	Rare
cBSA (extrinsic)	Xenoantigen immune MN	Infants and young children fed on cow's milk	1. Circulating cBSA 2. Anti-cBSA antibodies	IgG1 or IgG4	Staining for BSA within subepithelial deposits	Rare
PLA2R (intrinsic)	Primary MN	Adults Adolescents Young children Newborns	Anti-PLA2R antibodies	IgG4	Staining for PLA2R within subepithelial deposits	Adults and adolescents: ~70% of primary MN Young children: Uncommon Newborn: Rare, associated with anti PLA2R antibodies transfer across the placenta or by breast feeding
THSD7A (intrinsic)	Primary MN Associated with increased risk of malignancy	Adults Children	Anti-THSD7A antibodies	IgG4	Staining for THSD7A within subepithelial deposits	Adults: 3–5% of primary MN Children: Occurs but unknown prevalence
Exostosin 1,2 (intrinsic)	Lupus membranous nephropathy (class V)	Adults (young women)	Not detected	IgG1	1. Staining for EXT1 and EXT2 along the GBM 2. Tubulo-reticular inclusions	Adults: 16–30% of class V lupus nephritis, rare in primary MN Children: Not tested (youngest reported case: 17 yrs)
NELL-1 (intrinsic)	Primary MN or malignancy – Associated secondary MN	Adults	Anti-NELL-1 antibodies	IgG1	Incomplete staining for IgG and NELL-1 within subepithelial deposits	Adults: about 8% Children: Unknown
Semaphorin 3B (intrinsic)	Primary MN	Children, even 1–3 years of age, and young adults	Anti -semaphorin 3B antibodies	IgG1	1. Staining for semaphorin 3B within subepithelial deposits 2. Tubular basement	Children: 15% of non-lupus MN

et al. [5] used glycoproteins purified from glomerular extracts to detect antibodies that reacted only under non-reduced conditions with a 185-kDa protein in about 70% of samples from patients with “idiopathic” MN. This protein was identified by mass spectrometry (MS) as the M-type phospholipase A2 receptor (PLA2R).

In 2014, Tomas et al. [85] using similar methods identified a second target antigen, trombospondin type 1 domain-containing 7A (THSD7A), in a small subset of patients (3–5%). Both proteins induce an IgG4-predominant humoral immune response.

More recently, a major technological advance was achieved by [78] using laser microdissection of glomeruli followed by MS identification of trypsin-digested proteins. They started from kidney biopsies of MN patients double negative for PLA2R and THSD7A antigens. A major difference with the immunochemical methods previously employed is that these authors use paraffin-embedded biopsies, instead of sera, which allows identification of the antigen even in patients with immunologically inactive disease who have cleared the antibody from the circulation but not the antigen from the deposits.

Exostosin 1/exostosin 2 (EXT1/EXT2) are the first two proteins that were identified using this technology and subsequently detected by immunohistochemistry (IHC) along the GBM of patients with PLA2R negative MN. The first report by Sethi et al. describes 26 EXT1/EXT2-associated MN with features of secondary MN, including staining for IgA or IgM or both in addition to IgG (mostly IgG1). The majority of the patients (81%) exhibited clinical and biopsy findings suggesting autoimmune disease with positive serology like anti-nuclear antibody (ANA), anti-double stranded DNA, anti-SSA/SSB, or anti-ribonucleoprotein antibodies and biopsy that was positive for glomerular C1q deposition and tubuloreticular inclusion bodies.

In the validation cohort, EXT1/EXT2 stained positive in pure lupus membranous nephritis (LMN) (8/18 patients) but cases of lupus nephritis that did not have a membranous component were

negative for EXT1/EXT2, suggesting that EXT1/EXT2 are specific to LMN. The authors were unable to demonstrate circulating anti-exostosin antibodies in 20 patients with EXT1/EXT2-associated MN, consequently EXT1/2 cannot be considered as yet as an antigen, but as a biomarker. In practice, EXT1/EXT2 staining may help identify LMN when the renal involvement precedes the development of extrarenal manifestations of SLE and when serology for active SLE is negative [78]. A study by Hanset et al. further specified that EXT1/EXT2-associated MN is more prevalent in young women with features of systemic autoimmunity [37]. Currently, the youngest patient described with EXT1/EXT2 is 17 [78].

Subsequent antigens identified by this method were NELL-1 [80], semaphorin 3B (SEMA3B), [79], and NCAM1 [14].

NELL-1 is a 90 kDa secreted protein produced mainly by osteoblasts. In the normal kidney, NELL-1 is detected in tubular cells but not in the glomerulus. NELL-1 becomes deposited in the extracellular matrix between podocytes and GBM and colocalizes with IgG within incomplete global or segmental deposits. The predominant humoral response is carried by IgG1, IgG3, and sometimes also IgG2, but not by IgG4. Importantly, a possible association with cancer was described in the French and Belgian validation cohorts and confirmed by Caza et al. in the largest series of 91 patients reported so far, in which one-third of patients had a cancer [15]. The youngest patient found with NELL-1 associated primary MN was a 30-year-old female. At this time, it is unknown if NELL-1 MN exists in children.

Semaphorin 3B (SEMA3B)-associated MN represents a unique type of primary MN that is more likely to be present in pediatric patients, particularly in very young patients with onset <2 years old [79]. Eleven cases have been identified, 9 in children. Confocal microscopy showed that both IgG and SEMA3B co-localized to the GBM (Fig. 3, panels I, J, and K). In 4 of the total 11 diagnosed cases, kidney biopsy also showed a unique finding of IgG deposits along the tubular basement membrane and tubuloreticular inclusions. Antibodies were detected in 4/4 patients with active disease but not in the one patient in clinical remission. They are predominantly IgG1 and react with the recombinant protein only in reduced state, which suggests that novel or cryptic epitopes are triggered by environmental factors or under pathophysiological conditions.

NCAM1 was most recently identified to be the target antigen in 6.6% of a large cohort of patients with LMN (14/212) and rarely positive (2%) in a smaller group of patients with primary MN (2/101) [14]. In the MLN group, all but one girl (12y) were adults with a mean age of 34y. Anti-NCAM1 antibodies have been detected in the serum of patient with MLN but it is yet unknown whether anti-NCAM1 antibodies correlate with disease activity. One MLN case with dual EXT and NCAM1 positivity is described.

It is unclear what triggers the immune system against intrinsic antigens such as PLA2R and THSD7A. In other cases, the antigen, although intrinsic, does not likely originate from the podocyte but may shed from other areas or from cancer and initiate an immunologic reaction and the formation of circulating immune complexes that subsequently become deposited in the GBM. This seems to be the case of most antigens recently described.

Extrinsic Podocyte Antigens

The first observation that a food antigen could be responsible for MN was reported in children with cationic bovine serum albumin (BSA)-related MN [26]. Again, this observation was inspired by an experimental model described by Adler et al. and Border et al. [1, 13]. Some patients, mostly infants and young children (5 months–2.3 years of age in the initial disease description) with classic histological findings of MN were found to have high serum titers of anti-BSA antibodies reacting with one peptide region of BSA but not with human serum albumin. Biopsies showed subepithelial IgG deposits containing cationic BSA. Change in BSA basic electric charge may derive from industrial processing of milk or from intestinal microbiota. The immaturity of intestinal walls in very small children fed with cow's milk may allow small amounts of this dietary antigen into the circulation, leading to formation of anti-cationic BSA circulating antibodies. In the kidney, due to its positive charge, the cationic BSA antigen is attracted to the negatively charged GBM and gives rise to immune complexes in the subepithelial region [26].

An exceptional form of MN has been described in children affected with rare metabolic diseases such as mucopolysaccharidosis type 6 and Pompe disease, which are due to a genetic mutation causing the lack of a specific enzyme. These children can therefore benefit from enzyme replacement therapy (ERT). However, due to the absence of this enzyme in the patient, ERT proteins over time can become potential extrinsic antigens that trigger immunization [27, 44].

MN can develop **actively** when the immune system is triggered against an antigen intrinsic or extrinsic to the podocyte. Infrequently, it can also develop **passively** as in the cases of antenatal

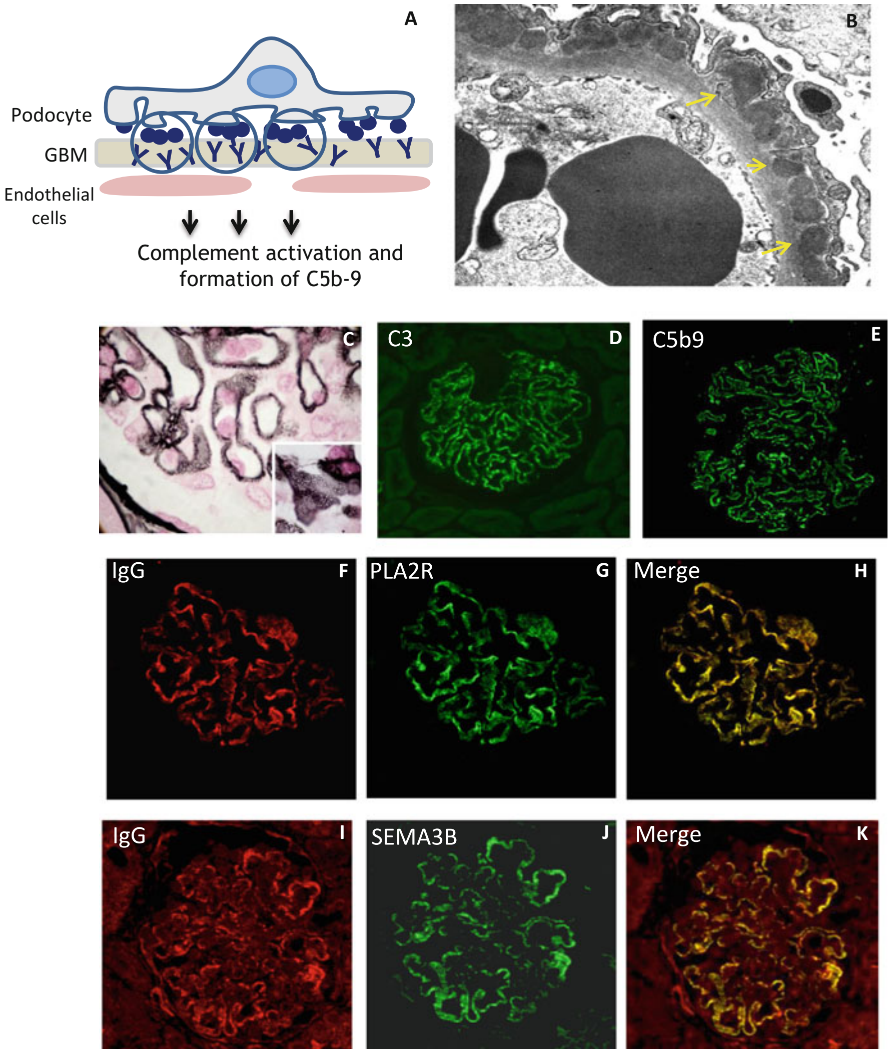

Fig. 3 Common histopathological pattern on kidney biopsy from MN patients. Panel A: Schematic representation of the mechanism of damage of the glomerular filtration barrier leading to proteinuria in MN. Blue solid circles represent the antigen at the podocyte surface, then contained with the bound IgG antibody (Y) coming from the blood in the immune complexes which are trapped in the subepithelial space. GBM = glomerular basement membrane. Panel B: Electron microscopy of a kidney biopsy of a patient with MN, the yellow arrows show the dense subepithelial immune complex deposits. Panel C: Silver stain of a kidney biopsy; by light microscopy, the thickening of the GBM is clearly visible with numerous spikes formed by expansion of the GBM with the appearance of numerous pinpoint "holes" in tangential sections, indicating deposits that did not stain with the silver stain (inset). Panels D and E: IF of C3 and C5b9 in a kidney biopsy of a patient with MN, showing staining along the GBM. Panels F–H: IF in a kidney biopsy of a patient with PLA2R-associated MN, showing IF positivity for IgG along the GBM in red (panel F), IF positivity for PLA2R along the GBM in green (panel G), and co-localization of the two in yellow (panel H). Panels I–K: IF in a kidney biopsy of a patient with semaphorin 3B (SEMA3B)-associated MN, showing IF positivity for IgG along the GBM in red (panel I), IF positivity for SEMA3B along the GBM in green (panel J), and co-localization of the two in yellow (panel K)

alloimmune MN associated with alloantibodies to neutral endopeptidase or transmission of anti-PLA2R antibodies from a mother to her fetus through the placenta and by breast milk [24, 75]. These passively developed cases of MN will recover when the route of transmission is removed.

Complement Activation and Podocyte Injury

The formation of immune complexes in subepithelial sites is central to MN resulting in complement activation identified by immunohistochemistry and more recently by MS [71]. Yet, the main deposited subclass is IgG4 that only weakly, if at all, activates complement pathways except in case of altered glycosylation. The amount of C1q is very low or undetectable in immune deposits of primary MN, indicating that activation of the classical pathway is not the main pathogenic mechanism. The presence of C4d in deposits in the absence of activation of the classical pathway suggests activation of the MBL pathway. Hayashi et al. found that the staining intensity of MBL correlated with the IgG4 staining intensity [38]. There is strong evidence that abnormally glycosylated IgG can activate the MBL pathway [61] and that PLA2R IgG4 can bind MBL [36, 96]. Glomerular deposition of factor B and properdin found in biopsies from MN patients provides evidence that both the alternative and lectin pathway can be involved. Cases of MN with MBL and ficolin deficiency have been reported, suggesting that formation of C5b-9 in those cases resulted mainly from hyperactivation of alternative pathway [3]. Moreover, MN was reported in a patient with C4 deficiency in which the classical and lectin pathways are not functional [53]. In contrast to PLA2R MN, the neonatal NEP form and NELL-1 and SEMA3B MN are mainly associated with IgG1, which activates the classical pathway, and C1q is found deposited in glomeruli in NEP and SEMA3B MN.

Complement activation and formation of the C5b-9 membrane attack complex (MAC) have major role in sublethal podocyte injury activating different mediators, such as phospholipases, protein kinases, cyclooxygenases, transcription factors, and cytokines. These signals influence podocyte cell metabolic pathways, structure and function of key cytoskeletal proteins and slit diaphragm, and DNA integrity [63, 82]. The injured podocytes produce new extracellular matrix. In addition to forming immune complexes, anti-podocyte antibodies may directly alter podocyte biology [72].

Gene Polymorphisms and Risk of Primary MN

MN is not a typical hereditary disease in Mendelian terms but there is growing evidence to support a strong genetic component. The initial genome-wide association (GWAS) study in 3 European cohorts including 556 patients of white ancestry found that primary MN in adults was strongly correlated with risk alleles, one in a noncoding single nucleotide polymorphism (SNP) within the *PLA2R1* gene (rs4664308) and another in the *HLA-DQA1* gene (rs2187668), a member of the HLA class II [81]. In individuals who were homozygous for both risk alleles, the risk of having MN was nearly an 80-fold as compared to individuals who had neither risk allele.

The same strong correlation between risk alleles (SNPs) of *PLA2R1* and *HLA-DQA1* and the risk of developing MN was found in a large Chinese cohort of 2132 individuals, including 1112 patients with IMN and 1020 healthy controls [58]. The authors concluded that patients with both risk alleles confer >11 times the risk of developing MN. They also correlated the presence of risk alleles to PLA2R antibodies.

Two studies performed on Chinese population revealed different HLA class II risk alleles associated with increased risk of MN [22, 51] and proposed that HLA associations may differ between ethnicities. This was reinforced in the largest international genetic study of MN performed recently. The study involved East Asian cohorts (1632 biopsy specimen – diagnosed cases and 3209 controls) and European-ancestry cohorts (2150 biopsy specimen – diagnosed cases and 5829 controls) [95] and found ethnic differences in HLA locus associations, defining *DRB1*1501* as a major risk allele in East Asians, *DQA1*0501* in Europeans, and *DRB1*0301* in both ethnicities. The *PLA2R1* locus (rs17831251) represented the most strongly associated non-HLA signal. In addition, this study identified two previously unreported loci, *NFKB1* and *IRF4*, linked to inflammation pathways. GWAS loci explain 32% of disease risk in East Asians and 25% in Europeans.

Clinical Features and Laboratory Investigations

The clinical presentation of MN is characterized by a variable degree of proteinuria, which can be asymptomatic, detected on routine urinalysis or more intense and quite frequently (25–100% of cases in different reports) in the nephrotic range, leading to NS (hypoalbuminemia, edema, hyperlipidemia). However, the onset of clinically evident nephrosis is usually more gradual than what is seen in minimal change disease, and asymptomatic nephrotic-range proteinuria has been reported in 16–38% of cases [16, 87]. Compared to adults, relapses tend to be more frequent. Moreover, while in adults microscopic hematuria can rarely occur, in children, it is frequently present (up to 70% of cases) [16] especially in children of Asian ancestry where it is reported in 90% of cases [86], while gross hematuria is reported in up to 40% of patients [52, 86]. Renal function is usually preserved [16], and hypertension is uncommon, but may be present in up to 36% of children at onset [92]. Thromboembolic complications, a serious complication of MN in adults, tend to be less frequent in children [57]. These features, together with the frequent association with concomitant associated causes (primarily HBV in endemic areas and SLE), differentiate MN in children from MN in adults (Table 3). Of note, a consistent group of children will receive a diagnosis of MN after having given several treatments (4–8 weeks of glucocorticoids), as they will have been initially treated for NS and then biopsied due to steroid-resistance.

Screening for infections, primarily hepatitis B and C, CMV and EBV should be performed. Other infections should be investigated based on the presence of associated clinical features.

Autoantibodies, in particular ANA and anti-dsDNA, should be performed in all cases. However, in the presence of isolated lupus nephritis without systemic features, particularly when anti-nuclear antibodies are negative, discriminating lupus nephritis with features of MN (class V lupus nephritis) from a primary form of MN can be challenging. In these cases, staining for EXT1/EXT2 and NCAM1 may be of great clinical use in predicting SLE (see below).

If systemic features are present, these will guide the search for other secondary causes (neoplasia, other autoimmune conditions such as systemic lupus erythematosus, Sjogren syndrome, Crohn's disease). A detailed history should be

Table 3 Differences between adult and pediatric forms of MN. (Modified from Ayalon R and Beck LH Jr. Membranous nephropathy: not just a disease for adults. Pediatr Nephrol. 2015 Jan;30(1):31–9)

Classification	Pediatric MN	Adult MN
Proportion of NS that is MN	1–15% from 2 to 18 years of age	15–50% from 18 to 50 years of age
Proportion of MN that is primary/idiopathic	Minority	Majority
Proportion of primary MN that is PLA2R-associated	45% (esp. adolescents)	70–80%
Clinical features		
Male predominance	No	Yes
Hematuria	70–90%	30–50%
Thromboembolic events	<5%	10–20%
Frequently relapsing course	Frequent	Rare
Progressive kidney failure	<25%	30–40%
Pathology		
Mesangial deposits	Infrequent in primary MN/ Frequent in LMN	Infrequent in primary MN/ Frequent in LMN
Segmental distribution of deposits	Seen	Rare
Deposits along the TBM	Typical of primary forms due to semaphorin 3b Abs in children, even <2 years of age	Extremely rare, seen in young adults with semaphorin 3b Abs

taken pertaining food and any medication, as mercury intoxication and a variety of medications such as penicillamine, infliximab, etanercept, tiopronin, captopril, and NSAIDs can trigger MN (see Table 1).

Histopathology

MN is a pathological term for lesions characterized by the accumulation of subepithelial deposits. These deposits are formed in the subepithelial space between podocytes and the GBM (Fig. 3, panel A) where they appear as electron-dense deposits by electron microscopy (Fig. 3, panel B). By *light microscopy*, these deposits cause thickening of the GBM. They are often associated with the formation of extracellular matrix around the deposits causing erect projections (spikes) that are better seen on Jones' silver stain (Fig. 3, panel C).

Composition of the deposits can be analyzed by *immunofluorescence (IF)*. They contain the complement component C3 (Fig. 3, panel D) and the complement terminal complex C5b-9 (Fig. 3, panel E) which contrasts with the quasi-absence of inflammatory cells in the glomerulus (most likely because complement activation occurs beyond the GBM in the subepithelial space). The deposits result in a fine granular pattern of polyclonal IgG staining along the capillary walls (Fig. 3, panels F and I). In some cases, deposits are segmental or global but incomplete, which suggests NELL1-associated MN although no pediatric case has been yet identified [15, 49].

Diagnosis of PLA2R-related MN can be established by IF (Fig. 3, panel G) or immunohistochemistry on paraffin sections stained with the relevant antibody. In forms of PLA2R-negative MN, staining for the other candidate antigens is recommended whenever possible to allow accurate diagnosis and therefore optimal management and monitoring (Fig. 3, panel J shows an example for semaphorin 3b). Antigen staining co-localizes with the polyclonal IgG staining (Fig. 3, panels H and K). IgG subclass determination is also relevant, as PLA2R-related forms have predominantly IgG4 while most cases associated with the recently identified antigens/biomarkers (EXT1/2, NCAM1, NELL1, and SEMA3B) have IgG1, and this determines downstream complement activation as detailed above.

MN can be divided into five stages by *electron microscopy* based on the position and radiolucency of the deposits. Initially, there were four stages 1–4; however, recently stage 0 has been added: Stage 1 – small and sparse subepithelial deposits without spikes or thickening of the GBM; Stage 2 – more extensive subepithelial deposits separated by projections of newly formed matrix material (spikes) between the deposits with thickening of the GBM; Stage 3 – deposits completely surrounded by basement membrane (intramembranous deposits); Stage 4 – deposits undergo absorption and become electron-lucent; and Stage 0 – no electron-dense deposits. This indicates a very early disease where LM appears normal but IF shows presence of IgG ± C3 staining in a capillary-loop pattern. This can be seen in recurrent MN posttransplantation by protocol biopsy. Of note, this staging system does not correlate with the clinical presentation (e.g., degree of proteinuria or prognosis).

Diagnosis, Serology, and Kidney Biopsy Staining

The diagnosis of MN has changed substantially in the last decade with the growing identification of podocyte antigens and associated biomarkers. Table 2 summarizes all the currently known antigens/biomarkers involved in MN and includes the MN category, the age group in which the antigen has been described, the serum finding and tissue staining for diagnosis, and prevalence based on published data. While ELISA and indirect immunofluorescence (IIF) assay for PLA2R-associated MN and IIF for THSD7A-associated MN have been developed commercially for detection and quantification of serum antibodies making diagnosis accessible to clinicians, for the other antigens this is not yet available. However, tissue staining for the latter antigens should be performed whenever possible.

Figure 1 represents the most likely forms of MN at different ages. Based on the prevalence of PLA2R-associated MN >10–12 years of age, it is reasonable to suggest performing an anti-PLA2R ELISA before a kidney biopsy in an adolescent with atypical presentation or steroid-resistant proteinuria (see below). In cases with a positive ELISA (>20 RU/ml), a biopsy is not required in the absence of deterioration of renal function and/or suspicion of a secondary cause [12].

The majority of MN cases can now be classified according to antigenic specificity (Table 2). In addition, they can be classified according to the cause. MN can be termed **primary** when the disease is associated serologically with antibodies to a known podocyte antigen. The term **idiopathic** MN is referred to cases in which the target antigen is yet unknown and serum antibodies are not recognizable and the disease does not appear to be secondary. **Secondary** MN is identified when the histologic lesion of MN can be associated with other systemic illness or exposures and the management relies primarily on treatment of the underlying cause of disease. However, the distinction between **primary** and **secondary** forms is somewhat artificial because finding specific antibodies or antigen staining in tissue does not rule out a secondary cause. On the contrary, finding EXT1/2 or NCAM1 suggests the diagnosis of MLN, finding THSD7A and NELL-1 suggests some forms of cancer in adults, and PLA2R positivity can coexist with hepatitis B, sarcoidosis, and cancer. One also should keep in mind that all **primary** forms have a cause triggering the immune response. The term **idiopathic** MN will become obsolete within a few years when all the antigens will have been identified.

Operationally, the discrimination of **primary** from **secondary** MN is currently justified because secondary forms may benefit from targeted treatment (i.e., SLE, cancer or hepatitis B). On the other hand, knowing the involved antigen may guide treatment (i.e., interrupting cow's milk or ERT) and allow accurate disease monitoring (i.e., anti PLA2R antibody titers, see below).

PLA2R-associated MN

M-type phospholipase A2 receptor (PLA2R) is the major antigenic target in adult primary MN. Circulating autoantibodies to PLA2R are found in 70% of cases [5].

The high prevalence and almost 100% specificity of anti-PLA2R autoantibodies in adult primary MN have given rise to the development of two FDA-approved serological tests for diagnosis and monitoring of disease activity. The first is an ELISA that gives a range of titers from less than 2 up to 1500 RU/mL, the second is a cell-based IIF assay which is more subjective and semi-quantitative, but has a higher sensitivity for low titer antibodies. ELISA titers below 20 RU/ml are considered negative according to the manufacturer [56, 84].

The prevalence of anti-PLA2R in adolescent patients with primary MN has been suggested to be similar to adult patients (81.1% in 11 children aged 13–17 years), while it is rare in children below 10 years of age [98]. An observational cohort study from India, also focusing on adolescents (10–19 years old) with primary MN, found that 83% had PLA2R-associated disease, as evidenced by glomerular staining for PLA2R on biopsy (14/18) and/or seropositivity for anti-PLA2R (13/18). Moreover, the levels of anti-PLA2R were associated with clinical status, suggesting that anti-PLA2R titers could be used to monitor immunological disease activity in children and adolescents, as in adults [50].

PLA2R-associated MN can also be diagnosed at the kidney tissue level by demonstrating the presence of the antigen within the immune deposits. In PLA2R-associated MN, we expect a prominent fine granular peripheral capillary wall pattern (Fig. 2, panel G) that can be co-localized with IgG (Fig. 2, panel H) and C3. In other MN cases that are non-PLA2R-associated or in normal controls, the PLA2R staining will be faint and localized to the podocyte, being absent from the immune deposits.

Recently, several algorithms have been suggested for the clinical use of the autoantibodies and the tissue staining [12, 23]. In the majority of PLA2R-associated MN with proteinuria, serum anti PLA2R antibody titers by ELISA and tissue PLA2R staining by IF of the immune deposits in the kidney biopsy are both positive. However, in some situations, the biopsy stains positive for PLA2R while the serum is negative for the antibodies. This situation more commonly arises at recovering disease, after the decline and disappearance of circulating antibodies, and explains the time that is required between immunologic resolution and clinical recovery. However, this same situation can rarely happen very early in the disease when the kidney is acting as a "sink" and is binding the majority of the autoantibody from the circulation [89]. This latter scenario often "seroconverts" to a positive anti-PLA2R status with time. Hence, in case of seronegativity for anti-PLA2R with positive PLA2R IF, close monitoring of proteinuria and serum antibody is necessary to distinguish between these two possibilities. This will allow to distinguish patients who are most likely to benefit from treatment from patients who might undergo spontaneous remission prior to treatment.

PLA2R-associated MN can recur after kidney transplantation. Kidney failure from MN in the pediatric population is rare but more frequent in adults. A few studies in the adult population suggest that higher levels of anti-PLA2R antibodies at the time of kidney transplantation increases the risk of recurrent MN [35]. This indicates that anti PLA2R antibodies may be pathogenic and suggests to delay transplantation and/or provide immunosuppressive treatment to allow transplantation when anti-PLA2R antibodies are no longer detectable.

Thrombospondin Type-1 Domain-Containing 7A (THSD7A)-Associated MN

THSD7A is the second antigen to be identified in primary MN. TSHD7A is much less prevalent than PLA2R, accounting for approximately 3–5% of adult patients with primary MN. THSD7A occurs in children but its prevalence in the pediatric population is unknown. Zaghrini and colleagues reported on a 4-year-old with anti-THSD7A antibodies that responded clinically and immunologically (antibody decline) to treatment with rituximab [97]. Similar to PLA2R, a simple IIF blood test for anti THSD7A may allow the diagnosis of primary MN. In addition, the presence of THSD7A antigen within immune deposits can be assessed using commercial antibodies to THSD7A. Commercial assays for anti THSD7A autoantibodies by ELISA are in the pipeline.

Although rare, double positivity to both autoantibodies and antigens to PLA2R and THSD7A has been described. Zaghrini et al. reported on a cohort of 49 MN adult patients positive to THSD7A (prevalence of 2.8% of primary MN) of whom 8 were also positive to PLA2R [97].

In the adult, positive staining for THSD7A can coexist with malignancy [43]. Hanset et al. found 50% solid organ malignancy in six patients with TSHD7A-associated MN. The three patients with tumor-associated MN had partial or complete remissions following treatment for their tumors [37]. Therefore, in adult patients with THSD7A-associated MN, aggressive screening for cancer should be pursued [8, 23, 65]. However, association with malignancy has not been described yet in children.

Prognostic Indicators and Treatment

The therapeutic approach to a child with MN should focus on the clinical condition and age of the patient and on the disease subtype (Fig. 1). Secondary forms, most frequently identified by screening for hepatitis B, C, and for ANA and anti-dsDNA antibodies and systemic features for SLE, must be approached by managing the underlying cause. For the correct management of lupus nephritis, see chap. Lupus nephritis. For the best approach to other secondary forms, see the specific section below. Due to its low prevalence in the pediatric population, evidence from randomized controlled trials enrolling children with MN are lacking. Therefore, it is particularly important that children with such a rare and potentially difficult condition be managed by experts in pediatric nephrology, using a personalized approach. Treatment of a patient with asymptomatic proteinuria should differ from that of a child with steroid-resistant nephrotic syndrome, weighing the risks against the benefits. The therapies to be evaluated range from supportive therapies to immunosuppressive therapies with potentially greater side effects.

The natural history of the disease in children and its long-term outcome is unclear, and it is not evident whether studies performed in an adult population, with a much higher incidence of comorbidities and a much lower life expectancy, can be extrapolated to children. While in adults the rate of spontaneous remission is reported to be between 30% and 40% [67], and conversely approximately one-third of patients described in historic cohorts progressed to terminal renal failure [34], in children similar historic cohorts (reviewed in [62]) and more recent studies [92] seem to suggest a more benign prognosis compared to adults. However, about 20% of pediatric cases reach end-stage renal disease [16, 52].

In children, predictors of outcome are not well defined; however, overall, some evidence indicates that nephrotic syndrome at onset [59], degree of proteinuria, hypertension, and interstitial fibrosis on the kidney biopsy may be correlated with a more severe outcome [16, 92].

In adults with primary PLA2R-associated MN, low/negative serum titers of circulating anti-PLA2R antibodies have been found to be positive prognostic factors and to predict spontaneous remission [42, 94]. The prognostic value of circulating antibody titers has been shown also for anti-THSD7A, and it appears likely to be of use in monitoring all primary forms of MN. Also in children with primary anti-PLA2R-associated MN, therefore, it is reasonable to assume that monitoring anti-PLA2R antibody titers can also be of clinical relevance in guiding therapeutic decisions and predicting spontaneous remission [2]. Though the availability of these assays may be limited to pediatric nephrologists especially in certain settings, their use should be implemented as widely as possible moving forward to avoid overexposing patients to potentially toxic immunosuppressive therapy once immunological remission is achieved. Drop in proteinuria may be seen long after (months to years) the decline and disappearance of anti-PLA2R antibodies. This can be explained by the time required for the kidney tissue to clear the deposits and to regenerate [6, 7].

Conservative Treatment

All children with significant proteinuria (>0.2 g/day or 0.2 g/g urine protein/creatinine ratio) should receive conservative treatment with ACE-inhibitor or angiotensin-receptor blocker at maximal tolerated dose. Evidence from adult studies [67] suggests that spontaneous remission was more frequent with lower baseline proteinuria. In this study, 80% of patients in spontaneous remission group were on ACEi/ARB compared with the group that did not attain spontaneous remission, in which only 60% were on ACEi/ARB. Dietary salt restriction is also necessary. In case of hypertension, the use of RAAS inhibition can have the dual benefit of anti-proteinuric and anti-hypertensive effect.

In adults, current guidelines [33, 93] suggest to employ antiproteinuric therapy in all MN patients, and to “wait and see” without adding immunosuppression for 6 months (so-called “wait and see” period) unless the patient has persistent nephrotic-range proteinuria (>4 g/day), reduced renal function, and/or additional risk factors for disease progression and/or serious complications (i.e., thrombosis). Immunosuppression is introduced in high/very high-risk adults at onset and subsequently if the patient fulfils the criteria for at least moderate risk children and proteinuria remains > 4g/day. In children, frequently upon diagnosis made by kidney biopsy, the child has already received some weeks of glucocorticoid therapy. Even in cases where the kidney biopsy precedes all therapeutic intervention, despite the reassuring historic data on outcome of MN in children, pediatric nephrologists tend to have a more proactive approach for the treatment of this disease with immunosuppression than adult nephrologists. Unless proteinuria is very low, immunosuppressive therapy is often used early after diagnosis. No evidence exists to inform this decision, which must take into account the age, general conditions, comorbidities, and wishes of the patient or of the family. The choice of the optimal immunosuppressive agent must be tailored to the patient, but substantial changes in the recommended therapeutic approach in adults, due to the completion of large studies, must be taken into account also in the management of children.

Glucocorticoids

Currently, no clinical trials evaluating the use of prednisone or equivalents in idiopathic MN and in children exist. Evaluating the effectiveness of this approach is made difficult by the fact that quite often a kidney biopsy diagnosing MN in children is performed for steroid-resistant nephrotic syndrome, after the patient has already received 4–6 weeks of full-dose oral prednisone and in some cases 3 methylprednisolone i.v. pulses. Therefore, children with MN who respond well to treatment with oral glucocorticoids may never be biopsied and therefore identified. Other pediatric patients, most likely due to older age at onset of proteinuria, will receive a diagnosis by kidney biopsy without previous glucocorticoid treatment. Moreover, in contrast to steroid-sensitive forms of nephrotic syndrome, which respond to glucocorticoids in days to weeks, MN is a disease that resolves much more gradually, and complete remission either spontaneous or induced by therapy normally requires months to years [42, 67]. In adults, evidence for the effectiveness of glucocorticoid monotherapy at disease onset does not support its use [18, 93]. In children, there is little evidence for the use of steroid monotherapy, although some small case series suggest that this approach may be effective. Valentini et al. demonstrated in a small series of idiopathic MN that, while 50% of the cases do not respond to steroids, there was complete or partial response in the remainder [87]. Similarly, in a series of 75 pediatric patients who underwent kidney biopsy for a non-MCD-like picture, 11 (14.7%) had MN. Of these, 8 were steroid sensitive and 3 were resistant [2]. Therefore, most children with intense or nephrotic-range proteinuria and MN receive at least 4 weeks of oral prednisone/prednisolone at doses used for steroid-sensitive nephrotic syndrome, followed by a tapering on alternate days for a total of at least 8–12 weeks. A second-line immunosuppressive treatment, most frequently a calcineurin inhibitor or rituximab, is frequently added.

Cyclophosphamide

Alkylating agents, mainly cyclophosphamide (CyC), have been extensively studied in the adult population with MN. While available evidence does not support their use as monotherapy [29], regimens employing i.v. methylprednisolone pulses followed by oral prednisone for 30 days followed by oral chlorambucil/cyclophosphamide for 30 days on alternate months for a total of 6 months have been shown to be clearly superior to conservative therapy in adults with MN and nephrotic syndrome. Cyclophosphamide was preferable to chlorambucil in terms of safety (reviewed in [18]).

In children, a small case series using cyclophosphamide for 12 weeks in addition to alternate day oral prednisone showed a good response [87]. However, cyclophosphamide, especially in young patients and females, is associated with two dangerous side effects: increased risk of neoplasia (bladder and hematologic) and gonadal dysfunction [46, 74]. In a recent retrospective investigation of treatment strategies employed for children and adults with MN in North America, 0% of children received cyclophosphamide in the first 6 months from diagnosis, and only 1 (3%) subsequently [64]. Given the concern for gonadal suppression and other adverse effects, it is our opinion that alkylating agents should be avoided in most, if not all, cases of pediatric MN if calcineurin inhibitors or rituximab are available as treatment options.

Calcineurin Inhibitors

Calcineurin inhibitors in combination with glucocorticoids have been used extensively in adult MN. There is some evidence from adult studies suggesting that tacrolimus may be more effective than cyclosporin A [68].

Several studies including randomized-controlled trials have shown that remission of proteinuria in tacrolimus-based therapy was comparable to that of cyclophosphamide and glucocorticoid [17, 39, 69]. These results, added to the more favorable safety profile of calcineurin inhibitors (CNI) compared to alkylating agents and to the greater familiarity that pediatric nephrologists have with CNIs, have led to their use being relatively frequent in children with MN. However, evidence of their effectiveness is tempered by the repeated finding of about 50% relapse of proteinuria following their discontinuation in children with MN. When initiating a CNI for MN, prednisone is usually given at standard doses used in steroid-sensitive nephrotic syndrome (60 mg/m2/day) for 4–6 weeks total (i.e., taking into consideration the dose taken pre-kidney biopsy in those children who were biopsied for steroid resistance), then tapered and discontinued over 3–6 months. CNIs are given for at least 6–12 months and need to be tapered very gradually to prevent relapse. Monitoring of blood doses is useful, and if no improvement in terms of proteinuria is seen after 6 months, CNIs should be discontinued and an alternative approach attempted.

Anti-CD 20 Monoclonal Antibody: Rituximab
The discovery of a number of circulating antibodies forming the immune complexes found in the subepithelial space in primary MN, especially anti-PLA2R, but also anti-THSD7A, and more recently and relevantly to the pediatric population, anti-SEMA3B has been a major progress of nephrology in the last decade. This finding has clearly provided a pathophysiological rationale for the use of B-cell depleting agents in primary MN, in order to reduce circulating antibodies and therefore the formation of the immune complexes that leads to damage of the glomerular filtration barrier and to proteinuria. In particular, rituximab has been shown to be effective in at least two-thirds of adults with these forms on MN. The GEMRITUX trial was a multicentric randomized controlled trial performed in France, in which 77 patients with normal renal function were randomized to either rituximab (375 mg/m2 on days 1 and 8) or continuation of non-immunosuppressive anti-proteinuric treatment (NIAT) after a 6-month lead-in period of NIAT in each arm [23]. In the follow-up period after the first 6 months, in which the clinical difference was not significant, the remission rate in terms of proteinuria was of 65% in the rituximab group, compared to 34% in the control group. When assessing anti-PLA2R antibody titers at 6 months, they were significantly reduced in the rituximab group. This confirms that a reduction in antibody titers precedes the reduction in proteinuria and suggest that monitoring of titers can be used to predict the need for a repeat infusion. In terms of number of rituximab doses, Cravedi et al. [21] showed that a single dose, if capable of inducing total (<1% of circulating lymphocytes) B cell depletion at 7 days, is as effective as multiple doses in inducing remission of proteinuria. A retrospective cohort study comparing the use of rituximab with this approach to the use of glucocorticoids and oral cyclophosphamide according to a well-defined standardized protocol showed at 5 years no difference in terms of achieving complete remission, with a better safety profile in the rituximab-treated group [90]. More recently, the MENTOR trial results were published [31]. This randomized controlled study conducted in North America compared rituximab to cyclosporine, including 130 patients with at least 5 g/day of proteinuria. Patients were treated with rituximab (2 infusions, 1000 mg each, 14 days apart, repeated at 6 months in case of partial response) or cyclosporine (at a dose of 3.5 mg per kilogram of body weight per day for 12 months). At 12 months, 39 of 65 patients (60%) in the rituximab group and 34 of 65 (52%) in the cyclosporine group achieved complete or partial remission. However, at 24 months, 39 patients (60%) in the rituximab group remained in remission, while the rate of remission in the cyclosporine group had dropped to 20% (13/65) due to a large number of relapses after the cyclosporine was tapered and stopped. Therefore, while rituximab was found to be non-inferior to cyclosporine in inducing remission at 12 months, it was statistically superior at 24 months in terms of maintaining long-term remission. In addition, among patients with anti-PLA2R-associated MN, the decline in

anti-PLA2R autoantibody titers was more rapid and more intense in the rituximab group than in the cyclosporine group. In terms of safety, there were no surprises and both agents were comparably safe and well tolerated.

There are several additional randomized controlled trials (RCT), comparing tacrolimus-rituximab to methylprednisolone-cyclophosphamide [30] and rituximab to steroids with cyclophosphamide NCT03018535, [77] in MN. The former shows the superiority of cyclophosphamide-based protocols in the adult while the latter is inconclusive. The best timing, dose and frequency of rituximab infusion in the adult remain to be determined.

Based on this data and on the extensive experience acquired in the use of anti-CD20 monoclonal antibodies, especially rituximab, in children with nephrotic syndrome [70], the use of rituximab appears reasonable as a first-line immunosuppressive agent, when available. Evidence of its efficacy in childhood forms of MN is very scarce and limited to case reports [60, 97]. In terms of dosing regimen and timing of infusions, especially in adolescents, using the same regimen as is advised for adults is appropriate. In children below the age of 12, the dosing most frequently used is 375 mg/m2/dose.

Other anti-CD20 agents, such as ofatumumab, ocrelizumab, and obinutuzumab, have also been employed in adults with MN. For ofatumumab, a single case report of a very young adult (18 years of age) shows effectiveness and safety [66], but this agent is no longer commercially available in most countries. Monitoring of long-term side effects, in particular relative to vaccine coverage and hypogammaglobulinemia, is important especially when anti-CD20 depleting agents are used in younger children, as long-term hypogammaglobulinemia has been reported in children with nephrotic syndrome [19]. Another B cell modulating agents, belimumab, which reduces naïve mature B cells but has less impact on B cell memory, appears to be potentially effective at 2 years of follow-up, both in reducing anti PLA2R antibody titers and in reducing proteinuria in a pilot study performed on adults with primary MN and nephrotic-range proteinuria [4].

Use of Antibody Titers to Guide Treatment in PLA2R-Associated Forms of MN A common goal of immunosuppressors is immunological remission defined by disappearance of PLA2R antibodies, a condition that usually precedes clinical remission. Conversely, persistence of high levels of anti-PLA2R Ab or their reappearance is usually associated with no remission and a relapse, respectively [41, 73]. This clinicobiological correlation seems to hold true for all antigens defined as yet, although prospective studies are needed.

Anticoagulation

Thrombotic events have been shown to be more frequent in the adult population with MN, irrespective of the degree of nephrosis. For this reason, KDIGO guidelines [93] suggest the use of prophylactic anticoagulation if serum albumin is below 2.5 g/dl. While this recommendation is probably not applicable to younger children, it may be prudent in severely nephrotic adolescents with MN.

Treatment of Specific Forms

HBV-MN can remit spontaneously in immunologically competent children, with seroconversion and clearance of HBeAg from the circulation [11]. In adults, studies have shown the effectiveness of interferon α, adenine arabinoside [54] and lamivudine [83], and some reports of the use of interferon α and lamivudine exist also for the pediatric population [10, 32]. In patients with a viral response to lamivudine without an immunological response as measured by anti-PLA2R antibodies, rituximab can induce remission of NS but continuation of lamivudine is mandatory [9].

In *neonatal MN induced by anti-NEP alloimmunization*, spontaneous remission is usually observed due to the short half-life of maternal antibodies. Neonates born after a second pregnancy are at major risk because of dramatically increased levels of anti-NEP antibodies on reexposure of the mother to placental NEP antigen. In these cases, which may present AKI, exchange transfusion may be necessary to remove the antibodies rapidly [28]. Monitoring of pregnancies in NEP deficient mothers relies on ELISA of anti-NEP antibodies with determination of IgG1 and IgG4 subclasses [91].

In *BSA-induced MN*, eliminating this protein by adopting a dairy-free diet could be beneficial. Circulating anti-BSA antibodies and BSA antigen should be monitored during follow-up because they correlate with disease activity [26].

Abstract

IgA nephropathy (IgAN), defined by dominant immunoglobulin A glomerular deposits, is the commonest glomerular disease in children presenting with microscopic hematuria. Its prevalence varies from 10% to 40% accounting for renal biopsy criteria and screening school programs. The pathogenetic events include mucosal production of galactose deficient IgA1, IgG autoimmune response, circulation and deposition of macromolecular IgA1 followed by complement activation, glomerular inflammation, and damage. The characteristic pathology feature is mesangial enlargement, with hypercellularity and matrix expansion. Renal pathology lesions are scored according to the Oxford Classification (mesangial hypercellularity M; endocapillary hypercellularity E; segmental glomerulosclerosis S; tubular atrophy/interstitial fibrosis T, crescents C) providing the MEST-C score. The most characteristic presentation is macroscopic hematuria associated with upper respiratory tract infections, sometimes with overt nephritic syndrome. Most children have microscopic hematuria with or without asymptomatic proteinuria, while a few have nephrotic onset. The outcome is generally favorable within the pediatric age, and up to 9% develop renal failure by 15 years. However, mild cases of IgAN in children might be missed and manifest irreversible damage only decades later. Hypertension, persistent heavy proteinuria, and reduced glomerular filtration rate at presentation and the MEST-C score provide prognostication indications. Not all children with IgAN need treatment as spontaneous remission may occur in mild cases. In children developing proteinuria angiotensin system, inhibitors are the first approach, while corticosteroids are an option for children with worsening proteinuria despite treatment or in cases with clinical and pathology features indicating active and potentially progressive IgAN.

IgA nephropathy · Mesangial proliferation · IgA deposits · Galactose deficient IgA1 · Oxford classification

Introduction

IgA nephropathy (IgAN), first described by Berger and Hinglais in 1968, is defined by dominant or co-dominant IgA deposits in glomeruli [1] (Fig. 1). IgAN is the commonest glomerular disease not only in adults but also in children who undergo renal biopsy because of isolated microscopic hematuria or hematuria associated with non-nephrotic proteinuria [2].

The incidence of primary IgAN in children ranges from 5 and 140 per million/children/year

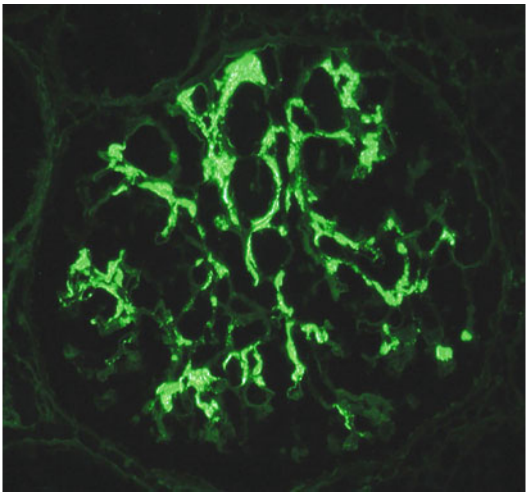

Fig. 1 Immunofluorescence micrograph showing mesangial IgA deposits in a patients with IgAN. Original magnification, ×400

similar to that in adults [3]. An international renal biopsy survey including 42,000 patients aged 0.1–100 years detected primary IgAN in 39.5% of renal biopsies in Asia, 22% in Europe, 12% in North America, and 6% in Latin America [4]. In children, IgAN represents 20–26% of renal biopsies in Europe [5], 17–20% in China, 14% in India, 10% in North America, 14% in South America, and 2.8% in Africa [6]. Conversely, IgAN is more frequent in Japan and Korea, where it represents 32% and 40% of renal biopsies in children [7, 8]. This variability may account for genetic and environmental factors, but most of all for school screening programs and variable criteria for performing renal biopsy. Renal biopsy follows the detection of urine anomalies by screening programs in some countries, while in others it is deserved to cases developing proteinuria [5]. In the large international cohort including patients of all ages, the different frequency of IgAN was related to the country of residence more than to the race/ethnic group [4], suggesting the role of environmental and lifestyle factors, as well as all local biopsy policies.

IgAN was initially considered a benign condition, but extended follow-up indicated a relevant progression over long term, involving 20–50% of all patients [9]. In children, the frequency of reaching renal failure within the pediatric age is limited by the short follow-up and increases when the observation is prolonged [10, 11].

Pathophysiology

Multiple mechanisms concur in the pathogenesis and progression of IgAN, including immunological, genetic, and environmental factors.

Genetic Factors

Familiar clusters of primary IgAN were reported in Kentucky and north Italy [12, 13]. Linkages of IgAN to 6q22–23, 4q26–31, 17q12–22 and 2q36 were observed, but no specific gene was identified. Several polymorphisms have been reported in association with IgAN development or progression, including genes encoding for Ig heavy-chain switch-region [14], core 1 beta1,3-galactosyltransferase (C1GalT1) [15], miR-146a [16], renin angiotensin system (RAS) [17], transforming growth factor-beta1 (TGFβ1) [18], platelet activating factor (PAF) acetylhydrolase [18]. Genome-wide association studies (GWAS) [19–21] have prioritized candidate genes implicated in the antigen processing and presentation pathway on chromosome 6p21 in the MHC region at three loci: (1) HLA-DRB1, -DQA1 and -DQB1, (2) HLA-DPA1, -DPB1 and -DPB2, and (3) TAP1, TAP2, immunoproteasome PSMB8, and PSMB9 genes [22, 23]. An increased expression of immunoproteasome, possibly regulated by these genes, was reported in patients with IgAN [24]. Other genes prioritized by GWAS are involved in the mucosal immunity pathway, including 22q12 (HORMAD2) locus, 8p23 α-defensin (DEFA) locus, 17p13 tumor necrosis factor (TNFSF13) locus involved in B cell development and class switching, 1p13 VAV3 locus (regulator of antigen presentation), 9q34 CARD9 locus (nuclear factor κB activation), 16p11 ITGAM and ITGAX (immune adhesion and phagocytosis), and the alternative complement pathway (chromosome 1q32 complement factor H (CFH) locus) [20, 23]. The association of CFHR3,1 deletion with reduced risk of IgAN [25] and altered serum levels of CFHR proteins detected in patients with IgAN [26] suggest a role for a dysregulated alternative complement pathway. Most loci associated with IgAN were also associated with immune-mediated inflammatory bowel diseases and mucosal response to intestinal pathogens, suggesting the hypothesis that the increased incidence of IgAN in some geographic areas might be consequent to a protective adaptation to mucosal invasion by intestinal pathogens [23]. A total of 15 IgAN susceptibility loci explained the overall risk of developing IgAN in 6.2% of European and 7.6% of Asiatic patients indicating the role of epigenetic factors.

Circulating IgA Molecules

The pathogenesis of IgAN is due to glomerular deposition of circulating IgA immune complexes (IgAIC) as indicated by electron-dense deposits in the mesangium coincident with IgA and C3 positivity. The role of macromolecular circulating IgA is supported also by the recurrence of IgAN in allografts and the disappearance of glomerular IgA in kidneys with subclinical IgAN transplanted by chance to non-IgAN patients [27].

IgA is the predominant class of immunoglobulin in mucosal secretions, where it consists mostly of dimers (polymeric IgA) [28]. In plasma, 90% of IgA is monomeric. Two isotypes IgA1 and IgA2 differ for a long insertion of amino acids at the hinge region between the CH1 and CH2 domains, which is present only in IgA1. IgA1 is the most frequent isoform in plasma, while both subclasses are found in secretions. IgA in renal deposits is mostly polymeric IgA1 [28]. IgA1 presents at threonine and serine residues in the hinge region insertion six short O-linked oligosaccharide chains (Fig. 2). A core N-acetyl galactosamine (GalNAc) occurs alone or is extended with β1,3-linked galactose (Gal) by C1GalT1 (which needs a specific chaperone, Cosmc) and covered with sialic acid in α2, 3 and/or α 2, 6 linkage [28]. In patients with IgAN, there is prevalence of IgA1 O-glycoforms consisting of GalNAc alone or sialylated [29–32]. This galactose-deficient IgA1 (Gd-IgA1) can form macromolecular self-aggregates and elicit IgG autoimmune response [33]. IgG antibodies recognize GalNAc-containing epitopes on Gd-IgA1, which cross-react with bacterial or viral cell-surface GalNAc residues. IgAIC constituted by Gd-IgA1 likely escapes clearance by hepatic receptors [34] and has a preferential renal deposition by virtue of enhanced lectinic reactivity with fibronectin, laminin, and collagen within the mesangial matrix [35].

Fig. 2 IgA1 molecules with hinge region *O*-glycosylation sites. IgA1 molecules have two heavy chains with three constant region domains CH1–CH3 and a hinge region between CH1 and CH2. Each serine (Ser) and threonine (Thr) residue is a potential site for an *O*-glycan side chain. Although there are nine potential glycosylation sites, IgA1 contains up to six *O*-glycans per hinge region. *O*-glycosylation sites consist of N-acetylgalactosamine (GalNAc) *O*-linked to Ser or Thr residues of hinge region. The largest *O*-linked saccharide of IgA1 is a tetrasaccharide with GalNAc, galactose (Gal) and two sialic acid residues. Aberrant IgA1 molecules with Gal-deficient *O*-linked glycans can contain terminal GalNAc or sialylated GalNAc at one or more sites. Pro, proline

The multihit hypothesis of the pathogenesis of IgAN [36] (Fig. 3) considers as first step the aberrant synthesis Gd-IgA1, followed by a second hit of antiglycan antibody response, the formation of circulating IgA1IC (third hit), and their glomerular deposition, with complement activation, inflammation, and glomerular damage (fourth hit). In both children and adults, Gd-IgA1 are increased in circulation [37, 38] but also in healthy relatives, suggesting that elevated serum levels of Gd-IgA1 are heritable [39].

An additional role can be played by the interaction between human IgA1 and CD89, the soluble form of the IgA receptor [40]. The IgA1–CD89 complex interacts with transferrin 1 receptor (CD71) and transglutaminase 2 receptors (TGase2) expressed on mesangial cells leading to immune deposits and inflammation [41]. The deposition of Gd-IgA1IC and IgG/IgA1IC in the mesangial area, possibly amplified by the CD89 system, induces the release of inflammatory mediators and activates the complement pathways (Fig. 4). This results in mesangial proliferation, extracellular matrix expansion, oxidative stress, and inflammatory cells infiltration. Podocyte injury and apoptosis follows, mediated by mesangial messages and this induces glomerulosclerosis [42], while glomerular-tubular crosstalk triggers interstitial fibrosis [43]. In this process, activation of the RAS system plays a crucial role [44].

Complement Activation

Involvement of complement in IgAN is indicated by glomerular deposits of common pathway factors, for example, C3 and C5b-9, and deposits of specific pathway markers, properdin, CFH (alternative pathway) and mannose binding lectin (MBL), ficolins (lectin pathway) [45]. Complement activation induces glomerular cell injury and inflammation, leading to disease expression and progression [46]. Polymeric IgA and aggregated IgA activate the alternative and the lectin pathways of complement, while Gd-IgA1 selectively activates the alternative pathway [47]. C4d deposits in absence of C1q indicate lectin pathway activation. Although C4d and MBL deposits are not coincident, the origin of C4d production is still

unclear [48]. The presence of C4d glomerular deposits is associated with progression of illness [49, 50]. These deposits co-localize with microangiopathic lesions in adults and children with IgAN and IgAN vasculitis [51]. Recent data have focused attention on subtle dysregulation of the alternative complement pathway in IgAN that represents a risk for progression [52, 53].

Innate Immunity, Mucosal Immunity

The feature of gross hematuria coincident with mucosal infections and detection of polymeric IgA in glomerular deposits has suggested mucosal immune response to environmental antigens as the first event in the pathogenesis of IgAN [54]. Mucosal IgA production is induced in the mucosal associated lymphoid tissue (MALT) by T-cell-independent and T-cell-dependent mechanisms [55]. The mucosal adsorption of intraluminal antigens triggers toll-like receptors (TLR), dendritic cell activation and synthesis of interleukins (IL-6, IL-10), TGF-β, B cell activating factor (BAFF), and APRIL (a proliferative inducing ligand). BAFF and APRIL, after binding to TACI (TNF receptor homolog transmembrane activator), actively promote the differentiation and proliferation of B cells with class switching from IgM to IgA [55]. Primed B cells migrate to the MALT effector area, the mucosal lamina propria, where they release dimeric IgA1 and IgA2. Renal deposits in IgAN mostly contain IgA1 subclass, which is a typical product of bone marrow plasma cells; hence, lymphocytes sensitized at mucosal level were supposed to migrate to bone marrow to differentiate into IgA1 producing plasma cells [56].

Several reports suggested that deposited IgA originate from mucosal challenge. The relationship between tonsils and IgAN was assumed after identification of disease, characterized by macroscopic hematuria shortly following pharyngotonsillitis with activation of the oral and Waldeyer pharyngeal ring (O-MALT). This hypothesis was supported by the cross-reactivity between antibodies eluted from the renal deposits of IgAN and tonsillar cells [57]. Tonsillar TLR9 was found to be more expressed in tonsils of patients with IgAN and it decreased after tonsillectomy [58]. Other studies failed to confirm the value of immune benefits of tonsillectomy in patients with IgAN [59].

The gut-kidney axis in IgAN [60] with dysregulated gut-associated lymphoid tissue (GALT) particularly represented by the Peyer patches was supposed after the observation of increased association of IgAN with celiac disease [61]. This hypothesis found a support in the GWAS study showing that most loci associated with IgAN are also associated with immune-mediated inflammatory bowel diseases, maintenance of the intestinal barrier, and response to gut pathogens [23]. Moreover, transgenic mice overexpressing BAFF develop hyper-IgA with IgAN conditioned by alimentary components and intestinal microbiota [62].

Intestinal microorganisms (microbiota) can modulate the GALT [63] and different microbiota patterns have been reported in patients with progressive IgAN [64]. In children and adults with IgAN, an increased intestinal permeability has been reported [65, 66] together with high levels of IgA anti alimentary antigens [38, 67]. Chronic enteritis was reported as second cause of mucosal infections in 35% of cases of IgAN from China [68], and this may favor increased release of bacterial lipopolysaccharide, which can methylate the chaperone gene Cosms, leading to production of Gd-IgA1 [69]. This hypothesis is supported also by increased expression of TLR4 (lipopolysaccharide specific ligand) in peripheral mononuclear cells, in children and adults with IgAN [70].

Apart from microbes, the GALT may also be triggered by abnormal response to alimentary antigens. IgAN was reproduced in mice after oral challenge with various alimentary components [71]. Mice fed a gluten-rich diet had significantly greater IgA mesangial deposits than animals fed a gluten-free diet since birth [72]. IgA anti-alimentary components and IgAIC were reduced after gluten-free diet in subjects with IgAN [73]. The role of gliadin was recently confirmed in IgA1/CD89 double transgenic mice developing spontaneous IgAN, in which a gluten-free diet for three generations prevented IgA deposits. The same study reported in patients with IgAN high levels of antigliadin IgA associated with increased proteinuria. These data suggest a role of GALT hyperresponse to intestinal alimentary components or microbes [74, 75].

Pathology

Immunohistologic Findings

The diagnostic immunopathological pattern of IgAN is the presence of IgA in the glomerular mesangium as the sole or predominant Ig. IgA deposits often extend just beyond the mesangiocapillary junctions into the adjacent capillary walls (Fig. 1). Lesser intense deposits of IgG and/or IgM may be seen, with the same staining pattern as IgA. In Yoshikawa series, mesangial IgA deposits were associated with IgG in 32% patients, IgM in 8%, and both IgG and IgM in 11% [76]. C3 deposits were observed in a similar distribution pattern in 64% cases. The early components of the classical complement pathway, C4 or C1q, are absent. Fibrin- or fibrinogen-related antigens are found in a diffuse mesangial distribution in 25–70% of patients and may be one of the injurious agents in the glomeruli [77]. Although, in most patients, IgA is present only in the mesangial regions, in ~10% of patients it is also seen in the peripheral capillary walls. Capillary wall deposits, seen on immunofluorescence or electron microscopy, are associated with severe clinical features and poor renal outcome [78–81].

Electron Microscopy

Electron microscopic abnormalities are mainly observed in the mesangium, which is enlarged by a combination of increased cellularity and matrix. Electron-dense deposits are seen in almost all patients (Fig. 5). They are granular masses situated immediately beneath the lamina densa in the perimesangial region and expanded mesangium. The size and extent of mesangial deposits vary from patient to patient; in some patients, they are large and produce localized protrusions. Peripheral glomerular capillary wall deposits are also found in the subendothelial and subepithelial regions. Subendothelial deposits occur most frequently in the capillary wall adjacent to the mesangium, although they are also observed in the peripheral part of the loop. Subepithelial deposits are unusual in adult patients,

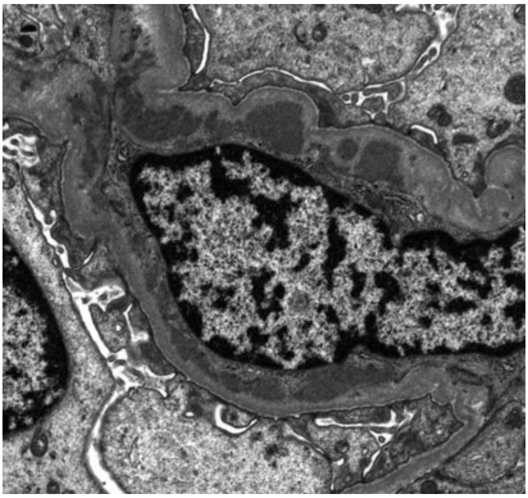

Fig. 5 Electron micrograph showing numerous electron-dense deposits in the mesangium in a patient with IgAN. Original magnification, ×5000

but are frequent in children with IgAN. They are small and flat and localized to a few capillary loops; humps typical of acute poststreptococcal glomerulonephritis are never seen. Lysis of the glomerular basement membrane is quite frequent in children [82]. In affected areas of the glomerular capillary, the lamina densa is thin and irregular, and the epithelial aspect of the glomerular basement membrane shows irregular segments of low electron density with an expanded, washed-out appearance. The epithelial foot processes are well preserved; diffuse foot process effacement may be seen in patients with nephrotic syndrome.

Light Microscopic Findings

Various glomerular changes are observed. The most characteristic abnormality is mesangial enlargement, caused by combination of hypercellularity and increase in matrix. Occasionally, small eosinophilic and PAS-positive fibrinoid mesangial deposits are also seen. Four types of mesangial change are identified in children with IgAN [83] (Fig. 6): (a) mesangial hypercellularity is more prominent than the increase in matrix, (b) the degrees of mesangial hypercellularity and matrix increase are similar, (c) the increase in matrix is more prominent than the mesangial cellularity, and (d) prevalent global glomerulosclerosis accompanied by reactive cell invasion. The first type of lesion is seen in biopsies in which the interval between onset of disease and biopsy is short. Serial pathologic observations reveal that prominent mesangial hypercellularity is almost exclusively seen in initial biopsies and decreases or disappears in follow-up biopsies. These observations suggest that predominant mesangial hypercellularity is characteristic of the early lesion of childhood IgAN and may disappear within a matter of months. An increase in mesangial cells is seldom striking in adult patients [84]. In contrast, biopsies with predominant matrix increase show a long interval between onset of disease and biopsy and a high percentage of glomerular sclerosis. Serial pathologic observations reveal that this type of change is usually seen in follow-up biopsies. An increase in the amount of mesangial matrix with duration of the disease has also been noted in adult patients [85]. These findings suggest that progression of IgAN leads to gradual decrease or resolution of mesangial hypercellularity and an increase of matrix associated with the development of sclerosis [86].

The severity of tubulointerstitial changes usually reflects the severity of glomerular damage. Vascular lesions, such as arterial or arteriolar sclerosis, are reported to be common in adults [87] but are unusual in children with IgAN [79]. This difference may be related to the age at biopsy and the duration of disease before biopsy.

Endocapillary hypercellularity is defined as an increased number of cells within glomerular capillaries, causing narrowing of the lumina. It may be present, in either focal segmental or diffuse distribution, and is typically associated with extension of deposits to peripheral loops. The hypercellularity might reflect proliferation, inflammatory cell infiltration, or endothelial cell swelling. Endocapillary lesions are more common in children and associated with active disease and high levels of proteinuria [88]. In IgAN, as in other proliferative glomerulonephritides, most of glomerular hypercellularity is due to leukocytes [89]. The presence of glomerular macrophages

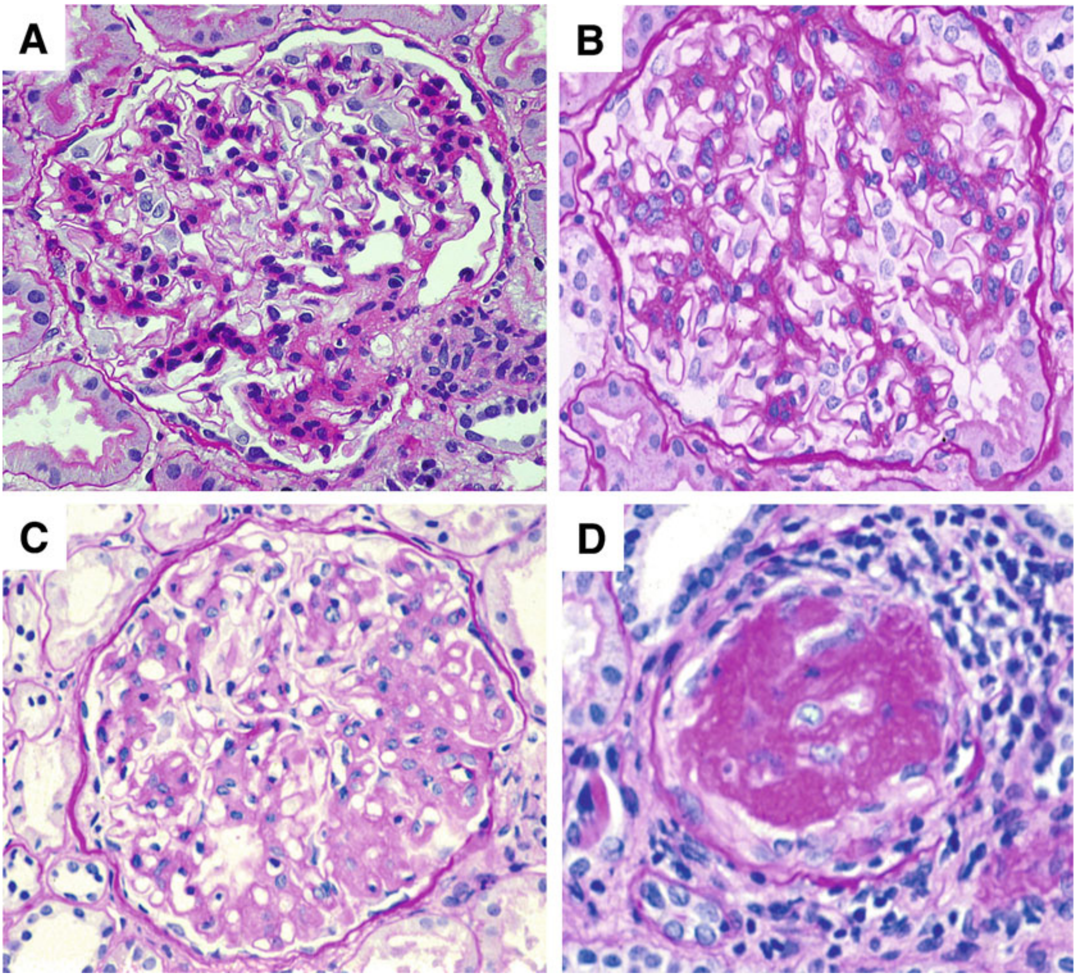

Fig. 6 Light micrograph showing mesangial proliferation in patients with IgAN. Four types of mesangial change are identified: (**a**) mesangial hypercellularity is more prominent than the increase in matrix. (**b**) The degrees of mesangial hypercellularity and matrix increase are similar. (**c**) The increase in matrix is more prominent than the mesangial cellularity. (**d**) Progression of IgAN is associated with the development of global glomerulosclerosis accompanied by reactive cell invasion. Original magnification, ×400

correlates with endocapillary hypercellularity and sclerosis [90].

Repeat Renal Biopsy

There have been only a few reports on the results of repeat renal biopsies [91, 92]. We previously reported our results in children with IgAN [93]. At the time of the second biopsy, 23 patients had showed clinical remission, defined as complete disappearance of proteinuria and hematuria with normal renal function, whereas 38 had persistent urinary abnormalities with normal renal function. There were no differences between the two groups with regard to the initial clinical and pathologic findings. The second biopsy of patients who were in clinical remission showed improvement of glomerular changes on light microscopy, a disappearance of or reduced mesangial IgA deposits, and lower amount of electron-dense deposits. Conversely, light microscopy showed a progression of histologic lesions and the persistence of both mesangial IgA deposits and electron-dense deposits in patients with persistent urinary abnormalities.

Shima et al. [94] have retrospectively screened and analyzed 124 consecutive children (age <18 years at first biopsy) with newly diagnosed severe IgAN showing diffuse mesangial proliferation, who received combination therapy (prednisolone + azathioprine or mizoribine + warfarin + dipyridamole, 90 patients) or prednisolone alone (34 patients) for 2 years and underwent repeat biopsies. After 2 years of treatment, 27 of the patients (21.8%) showed disappearance of glomerular IgA.

Differences Between Childhood and Adult Patients

Significant differences in the early glomerular lesions of IgAN between children and adults have been demonstrated [6, 95, 96]. Glomerular hypercellularity in mesangial area is prominent in children, and significantly greater than in adults. In contrast, glomerular matrix expansion and interstitial damage are more severe in adults compared to children. Glomerular hypercellularity correlated with proteinuria in children but not in adults, whereas glomerular matrix correlated with proteinuria and renal function in adults but not in children [95].

Oxford Classification

During past decades, many histologic classifications for IgAN were proposed, using semiquantitative or single-grade systems, and their utility in predicting renal outcomes. Although pathologic classifications provide valuable information for determining prognosis of IgAN, there is controversy as to whether these features add significant risk prediction to clinical features alone [97]. In 2009, the Oxford classification of IgAN reported the high predictive value of selected highly reproducible variables [98, 99] in patients with various age. The classification has obtained a considerable worldwide acceptance and was updated in 2016 [100]. The updated classification identified five key pathological features (mesangial hypercellularity, M; endocapillary hypercellularity, E; segmental glomerulosclerosis, S; tubular atrophy/interstitial fibrosis, T; and cellular/fibrocellular crescents, C) resulting in a MEST-C score that predicted renal outcome independently of clinical indicators at time of renal biopsy and during follow-up [98–100]. These findings are valid both for adults and children [100, 101].

Validation studies have demonstrated the clinical benefits and limitations and highlighted questions and difficulties of interpretation of biopsy specimens [102–109]. Findings from the VALIGA study, on 1147 patients with IgAN from 13 - European countries, have validated the Oxford classification across the whole clinical spectrum of the disease. Long-term follow-up of the cohort showed that the independent relationship between kidney biopsy findings and risk of progression towards kidney failure remains unchanged across age groups and decades after the renal biopsy [110].

Shima et al. [111] reported that a shorter time from onset to renal biopsy was associated with higher glomerular ratios of M, E, and crescents and lower ratios of S and G in 250 children with proteinuria >0.5 g/day/1.73 m^2 at biopsy, matching the inclusion criteria for IgAN of the original Oxford cohort. These findings indicate that acute lesions, such as M and E, reflect disease activity, with shorter times from onset to biopsy indicating severe disease activity. Crescents also reflect disease activity because crescents were acute lesions in their cohort. In contrast, chronic lesions such as S and G were absent early in course of disease, even in patients with severe acute lesions. Taken together, these findings suggest that each variable of the Oxford classification of IgAN may be influenced by the time from disease onset to renal biopsy and that differences in the significance of S and crescents between the original Oxford classification and other studies is due, at least in part, to differences in the timing of renal biopsy [111].

Finally, the most important clinical question is how we can make the Oxford classification more clinically relevant. Recently the International IgA Nephropathy Network used a large international collaboration of data sets with diverse ethnic representation to derive and externally validate a comprehensive risk prediction model in IgAN using readily available clinical and laboratory risk factors and the MEST-C score. The two adult prediction models were shown to be accurate and validated methods for predicting disease progression and patient risk stratification in adult multiethnic cohorts [112]. The updated pediatric prediction tool can predict the risk of 30% decline in eGFR or ESKD in children with IgAN [113].

Clinical Features

IgAN occurs at all ages but is most common during the second and third decades of life; it affects boys more often than girls, with the reported male to female ratio varying from less than 2:1 to 6:1 [114]. In a study of Japanese children [76], the mean age at presentation was 9.3 years in boys and l0.3 years in girls, and the male to female ratio was 3:2. The clinical presentation of IgAN varies. Some patients have asymptomatic microscopic hematuria with or without proteinuria. Other patients have recurrent episodes of macroscopic hematuria. Some patients present with acute nephritic syndrome and, more rarely, with acute renal failure.

Sixty-two percent of 258 Japanese children were found to have microscopic hematuria with or without asymptomatic proteinuria [76]. Twenty-six percent presented with macroscopic hematuria and 12% with an acute nephritic syndrome or nephrotic syndrome. Several studies from Europe and the United States reported that more than 80% of patients have episodes of macroscopic hematuria; recurrent gross hematuria is thus regarded as the hallmark of childhood IgAN [115–118]. However, it was the initial feature in only 26% of our series, presumably because of the school screening program that detected a high prevalence of asymptomatic urinary abnormalities rather than regional variation in the expression of IgAN. During the observation period, 60% patients had one or more episodes of macroscopic hematuria, whereas the other 40% were asymptomatic.

Macroscopic hematuria often occurs in association with upper respiratory tract infections; less frequently, it occurs in association with other infections involving the mucosal system (e.g., diarrhea and sinusitis). Episodes of macroscopic hematuria are sometimes associated with loin pain. The interval between the precipitating infection and the appearance of hematuria ranges from 1 to 2 days compared with 1 or 2 weeks in acute postinfectious glomerulonephritis. Many patients have recurrent episodes of macroscopic hematuria; each often associated hematuria is not with the same type of infection. The number of recurrences and the intervals between different episodes are variable. The incidence of macroscopic hematuria is lower in adults (Southwest Pediatric Nephrology Study Group) [118]. Emancipator et al. [119] summarized the previous reports of IgAN, in which most the patients were adults, and reported that 43% had macroscopic hematuria. However, in Japan, only 18–32% adult patients show macroscopic hematuria [120, 121]. The reason for the age-related differences is the incidence of macroscopic elucidated.

In asymptomatic patients, microscopic hematuria is almost always present and persistent. Proteinuria is common, and blood pressure and renal function at onset are normal. Patients with a nephritic or nephrotic onset have the most severe glomerular damage. Hypertension is infrequent and usually mild to moderate. Malignant hypertension is not a presenting feature in childhood. Nephrotic edema is reported in approximately 10% of patients. Acute renal failure is occasionally associated with episodes of macroscopic hematuria and is usually reversible. A number of investigators report a subset of patients with IgAN that is characterized by extensive crescents and a rapidly progressive course [121–123]. A review of published reports on crescentic IgAN revealed that 41% of patients with rapidly progressive glomerulonephritis were 16 years of age or younger [123].

Laboratory Investigations

Serum IgA levels are increased in 30–50% of adult patients but in only 8–16% children with IgAN [76]. For this reason, it is seldom of diagnostic significance. Serum complement component concentrations are usually normal, but the C3 level should be measured routinely if the patient has been referred for investigation after the first attack of hematuria to eliminate a diagnosis of postinfectious glomerulonephritis or membranoproliferative glomerulonephritis. Likewise, the antistreptococcal antibody titers should be determined after initial hematuria. These investigations are of little value when hematuria is known to have been present for more than 3 months. The serum creatinine should be measured routinely to estimate renal function and the estimated glomerular filtration rate should be determined. If present, proteinuria should be quantified, as proteinuria is associated with histologic lesions and a risk of progression. Plasma proteins should be measured routinely in the presence of heavy proteinuria.

Biomarkers

IgAN has been the focus of several studies aimed at identifying specific biomarkers. Serum galactose-deficient IgA1 level and glycan-specific autoantibody levels are prime candidates to become diagnostic biomarkers for IgAN because of their central role in the earliest stages of disease pathogenesis [124, 125]. However, although the serum level of galactose-deficient IgA1 is frequently elevated in patients with IgAN [37], the sensitivity and specificity of this laboratory finding are insufficient for the test to replace kidney biopsy as the diagnostic standard [2]. The serum level of glycan-specific IgG antibodies is correlated with the level of urinary protein excretion [126] and the risk of progression to end-stage renal disease or death [127]. This biomarker may prove useful for monitoring disease progression or the response to therapy [2].

Yanagawa et al. have reported that serum levels of galactose-deficient IgA1-specific antibodies are elevated in most IgAN patients, and their assessment, together with serum levels of galactose-deficient-IgA1, improves the specificity of the assays. These observations suggest that a panel of serum biomarkers may be helpful in differentiating IgAN from other glomerular diseases [128]; however, renal biopsy remains the only definitive diagnosis.

Urinary proteomic data are also candidates for diagnostic biomarkers because this approach can successfully differentiate patients with IgAN from healthy controls and from patients with other forms of renal diseases [2, 129]. Analyses of urinary samples by capillary electrophoresis with mass spectrometry have differentiated patients with IgAN from healthy controls and patients with minimal change disease or IgA immune complex nephritis due to chronic hepatitis C infection, even in association with nonpathologic proteinuria [2, 37, 126–132]. Furthermore, the urinary proteomic profile seems to predict the response to treatment with an angiotensin-converting enzyme inhibitor [133]. However, additional studies are needed to determine the potential and cost-effectiveness of urinary proteomic analysis in establishing the diagnosis of IgAN and making decisions about treatment [2].

Differential Diagnosis

The diagnosis of IgAN is based on the presence of IgA as the sole or predominant Ig in the glomerular mesangium. Because diffuse mesangial IgA deposits are observed in a variety of other disorders (Table 1), the diagnosis of IgAN can be made only by exclusion. IgA deposits are often incidental findings, and the pathogenesis and clinical significance are unclear.

Relationship Between IgAN and IgA Vasculitis (Henoch-Schoenlein) Nephritis

The relation between IgAN and Henoch-Schonlein nephritis (now IgA vasculitis nephritis, IgAVN) is complex. There is a close relationship between IgAN and IgAVN, with similar morphologic and immunopathologic features [134, 135]. The disorders are reported to coexist in different members of the same family, including a pair of monozygotic twins who developed the disorders

simultaneously after a well-documented adenovirus infection [136–138]. Moreover, the evolution of IgAN into IgAV in the same patient is described in both adults and children [139, 140]. It has been suggested that the two conditions are variants of the same process and that IgAN is IgAV without the rash [135, 138, 141]. Although there are similarities in their pathologic and immunologic features, the two conditions are clinically different, and the pathogenesis is not clear. Our study suggests that IgAVN is an acute disease, with glomerular lesions nonprogressive after the onset [142]. Therefore, in most patients, the prognosis is associated with the severity of glomerular change at the onset. In contrast, IgAN is a chronic, progressive glomerular lesion, which may eventually lead to progressive kidney disease, whatever the presentation. A few patients with IgAVN have recurrent episodes of macroscopic hematuria and progressive renal disease on repeat biopsies. Finally, IgAVN occurs mostly in young children and is rare in adults, whereas IgAN affects mainly older children and young adults. It is thus reasonable that these conditions be treated as different clinicopathologic entities until their pathogeneses is better understood.

Chronic Liver Disease

Glomerular IgA deposits may be observed in patients with various types of chronic liver diseases [143]. Mesangial proliferation and IgA deposits are the most common findings. Light, electron, and immunofluorescence microscopic features in patients with liver disease are similar to those in patients with primary IgAN. Most adult patients with chronic liver disease have clinically asymptomatic renal disease. Microscopic hematuria and mild proteinuria may be observed, but macroscopic hematuria, nephrotic syndrome, and impairment of renal function are rare. Glomerular lesions in children with chronic liver disease are very unusual. The pathogenetic mechanisms that contribute to mesangial IgA deposition in chronic liver diseases remain unknown. Significant elevations of the serum monomeric and polymeric IgA levels have been reported [144, 145]. Impaired hepatic clearance and increased synthesis of polymeric IgA, abnormal IgA metabolism, and portosystemic shunting of antigens and immune complexes are suggested as possible causes of mesangial IgA deposition in chronic liver disease [146].

Idiopathic Nephrotic Syndrome

A few patients with steroid-sensitive nephrotic syndrome show mesangial deposits of IgA on renal biopsy. They are classified by some as IgAN, whereas others consider that mesangial IgA in patients with minimal changes (i.e., without cellular proliferation) is coincidental. This probably applies to idiopathic nephrotic syndrome associated with mesangial IgA deposits occurring in

Asians and explains a favorable response to steroids, which is not the case in true IgAN [146].

Natural History and Prognosis

In adult series, the incidence of renal insufficiency varies from less than 10% to as high as 45% in long term follow-up in which 30–35% have been found to develop progressive renal insufficiency 20 years after disease initial discovery [114, 147, 148]. It can be estimated that 1–2% of adult patients will enter end-stage renal failure each year from time of diagnosis [149]. The long-term prognosis of 169 Japanese children with IgAN followed more than 10 years indicates that 9% of the patients had developed chronic renal failure by 15 years (Fig. 7).

Because of the variable rate of progression to chronic renal failure, there have been attempts to identify features present at the time of diagnosis that would predict the outcome. The following clinical findings are regarded as poor prognostic indicators in adult patients [114]: persistent hypertension, persistent heavy proteinuria, and reduced glomerular filtration rate at presentation [147, 148, 150–155]. In children, several studies have shown that the degree of proteinuria correlates with the severity of morphologic glomerular lesion [79, 117, 156], and heavy proteinuria at the time of biopsy predicts a poor outcome [80, 157]. In contrast, slight proteinuria or its absence at the time of biopsy predicts a favorable outcome [158]. Acute renal failure at onset is usually transient and associated with macroscopic hematuria and reversible tubular lesions. Males have been considered to have an unfavorable prognosis by some [147], but not all investigators [80, 159]. Schena et al. reported an increased risk of end-stage renal disease in familial IgAN [160].

Several pathologic features included in the MEST-C score are associated with a poor outcome as mentioned above, including diffuse mesangial proliferation; a high proportion of glomeruli showing sclerosis, crescents, or capsular adhesions; presence of moderate or severe tubulointerstitial changes; presence of subepithelial electron-dense deposit; and lysis of glomerular basement membrane by electron microscopy [80]. Patients with diffuse mesangial proliferation have been reported to have a significantly worse prognosis than those with focal proliferation or minimal lesions by light microscopy in adults [161, 162]. In many adult studies [87, 154, 159, 161], glomerular sclerosis and crescents have also been associated with poor renal outcome. Crescents were also associated with poor prognosis in children [117, 163]. Vascular lesions, such as arterial or arteriolar sclerosis, have been reported to play an important role in the

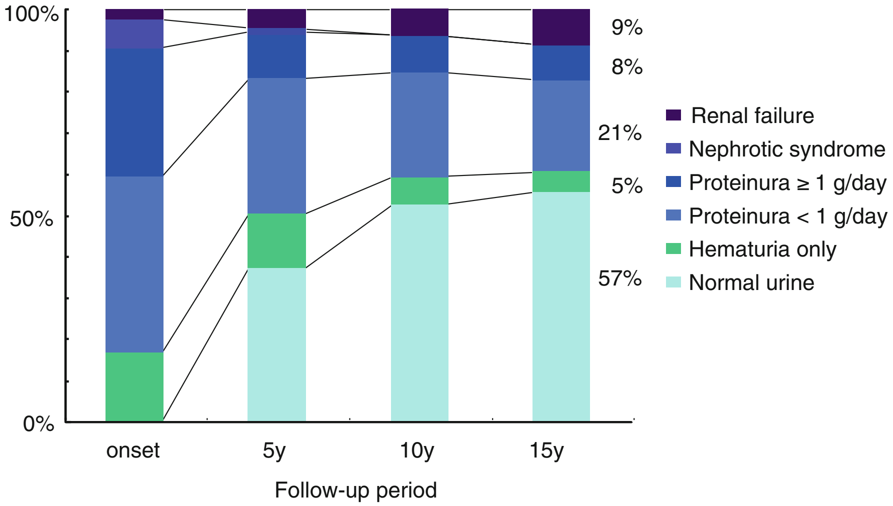

Fig. 7 Long-term prognosis of the 169 Japanese children with IgAN followed more than 10 years

progression of IgAN in adults. However, vascular changes are very unusual in children [83, 118, 122]. This difference may be related to the age at biopsy and the duration of disease before biopsy.

Our recent retrospective cohort study of 500 children with IgAN has showed an improved renal survival in Japanese children with IgAN, parallel to an increased use of angiotensin-converting enzyme inhibitors [164]. Among all patients, the actuarial renal survival was 96.4% at 10 years, 84.5% at 15 years, and 73.9% at 20 years. Diagnosed in 1976–1989, the renal survival was 94.0% at 10 years, 80.1% at 15 years, and 70.1% at 20 years. Diagnosed in 1990–2004, the renal survival was 98.8% at 10 years and 98.8% at 15 years ($P = 0.008$). In children with diffuse mesangial proliferation, both the 10- and 13-year renal survivals were 97.8% in 1990–2004, compared with 78.5% and 68.6%, respectively, in 1976–1989 ($P = 0.0003$). In the same study, prognostic factors for end-stage renal disease-free survival were analyzed [164]. The degree of mesangial proliferation and the year of initial renal biopsy were significant in both univariate and multivariate analysis. For children with IgAN, the most influential prognostic variable was the degree of mesangial proliferation. Proteinuria at diagnosis was significant in the univariate, but not in the multivariate analysis. Multivariate analysis showed that the initial renal biopsy year was a significant factor for renal survival independently of the degree of mesangial proliferation, proteinuria at diagnosis, and estimated creatinine clearance at diagnosis (hazard ratio = 0.08; 95% CI 0.004–0.43).

Some patients with IgAN achieve spontaneous remission even when not receiving medication. The retrospective study of 96 children with minor glomerular abnormalities or focal mesangial proliferation who did not receive medication showed spontaneous remission in 57 (59.4%) [165]. The cumulative spontaneous remission rates among these patients were 57.5% and 77.4% at 5 and 10 years from onset, respectively. The mean time from onset to remission was 5.9 ± 0.4 years. Of the 57 patients with spontaneous remissions, 10 (17.5%) also developed a recurrence of urinary abnormalities. The cumulative recurrence-free rates were 79.9% and 67.9% at 5 and 10 years, respectively, after remission. The spontaneous remission rate in childhood IgAN with minor glomerular abnormalities or focal mesangial proliferation was higher than expected [165]. These results suggest that physicians should consider the potential for spontaneous remission and refrain from aggressive treatment in IgAN patients with minor glomerular abnormalities or focal mesangial proliferation.

Long-Term Outcome After Renal Transplantation

IgAN may recur in approximately one-third of patients, more frequently in younger subjects and in those who had a rapid progression of the disease in the native kidney [27]. Overall graft survival rates at 5 and 10 years were 94% and 73% and the outcome was generally good in case of retransplantation [166]. Recurrence of IgAN did not affect the graft survival at over the first 10 years.

Management

Therapeutic Agents for Treatment

Renin-Angiotensin System Blockers

In children with IgAN, blood pressure control should be strict particularly when proteinuria is present. Blood pressure values must be targeted to the 50th percentile, as recommended by Kidney Disease: Improving Global Outcomes (KDIGO) Clinical Practice Guideline [167]. The medications of choice are either angiotensin-converting enzyme inhibitors (ACE-I) or angiotensin II receptor blockers (ARB) because they reduce blood pressure and proteinuria, and decrease mesangial cell activation through binding to specific receptors [44].

Coppo et al. performed a European multicenter RCT enrolling children and young patients (3–35 years old) with persistent proteinuria $>1 < 3.5$ g/day/1.73 m^2 [168] that were randomized to benazepril 0.2 mg/kg/day or placebo for 3 years. The primary outcome, identified by >30% decrease in eGFR and/or worsening of proteinuria to nephrotic range, was significantly better in the ACE-I group. A stable remission of proteinuria (<0.5 g/day/1.73 m^2) was observed in 56% of treatment group vs. 8% of placebo. On the basis of this trial and observations in adults [169], KDIGO suggested to treat children with IgAN and persistent proteinuria >0.5 g/1.73 m^2/day, with renin angiotensin system blockers. The effects of ACE-I in children with minimal proteinuria <0.5 g/1.73 m^2/day have not been investigated in randomized trials, but some benefits were suggested by a single arm collaborative Japanese observation over 2 years [170]. A recent RCT failed to show any benefit in adding ARB to ACE-I treatment in children with IgAN [171].

Glucocorticoids

The benefits of corticosteroids in IgAN reported in randomized trials in adults [172–174], led to the KDIGO suggestion that, if proteinuria persisted unchanged >1 g/1.73 m^2/day after 3–6 months of renin angiotensin axis inhibition, therapy with corticosteroids should be considered [167]. The KDIGO proposed a lower threshold of proteinuria to start corticosteroid treatment in children (>0.5 g/1.73 m^2/day). The statement was based on results obtained with 6 months regimens, using either three IV pulses of methylprednisolone (1 g) and oral prednisone (0.5 mg/kg on alternate days) [172], or oral prednisone 0.8–1 mg/kg/day for 2 months, with weaning over 6 months [173, 174]. Both protocols induced reduction in disease progression and proteinuria without serious side effects. A long-term legacy effect was observed after the pulse protocol [175]. No randomized controlled studies have been performed in children to validate these suggestions [176].

Some randomized trials in adults recently suggested a more cautious approach in using corticosteroids in patients with proteinuria and slow decline of renal functions. The STOP-IgAN trial [177] did not show a superior effect of immunosuppressive therapy (monotherapy with methylprednisolone pulses for 6 months in patients with eGFR >60 ml/min; combined treatment with oral prednisone and cyclophosphamide followed by azathioprine in patients with lower eGFR) versus supportive care for 3 years. The results at the end of the RCT were confirmed by a recent report after 10 years follow-up [178]. The original study as well as the follow-up report was underpowered to detect benefits of treatment because of the limited number of outcome events due to the slow progression of the illness in the cohort [179]. The Therapeutic Evaluation of Steroids in IgA Nephropathy Global (TESTING) study [180] randomized patients with proteinuria >1 g/day to either oral methylprednisolone or placebo. Recruitment was discontinued after 2 years because of excess serious adverse events (mostly infections, including two deaths) in 14% patients receiving corticosteroids versus 3% in the placebo group. While the preliminary results were consistent with potential renal benefit, early termination of the study did not allow any conclusions.

These recent studies in adults have influenced the most recent KDIGO guidelines for glomerulonephritis, which most of all address the severity of side effects and benefits of intensified supportive care [181]. The latter – not likely to be strictly adopted in children – consists of low-protein diet (0.8 g protein/kg/day), salt restriction, nicotine abstinence, treatment of metabolic syndrome, and blockade of the renin-angiotensin axis to achieve maximal blood pressure and proteinuria control. In normotensive children, the uptitration of ACE-I or ARB may be a challenge; similarly restriction of protein-intake might not be a suitable strategy.

In children, evidence-based reports on the effect of corticosteroids in treating IgAN are limited [176]. Uncontrolled observations or small studies in patients with varying baseline data and treated with different regimens provide conflicting results [182–184]. The best results were reported in severe cases with crescents successfully treated with pulse steroid therapy [184]. A placebo-controlled, double-blind randomized trial with prednisone (60 mg/m^2 every other day for 3 months, tapered to 30 mg/m^2 every other day for 12 months) or fish oil (4 g/day for 2 years) failed to show different outcomes [185]. However, the short follow-up, inequality of baseline proteinuria, and limited number of patients studied precluded valid conclusions.

Combined Corticosteroids and Immunosuppressive Medications

Some RCTs from the Japanese Pediatric IgAN Treatment Study Group supported the benefit of aggressive therapy in children with IgAN showing diffuse mesangial proliferation, which was considered per se a risk factor for progression. In these children, Yoshikawa's group performed the first pediatric RCT comparing a combination therapy (prednisolone, azathioprine, heparin-warfarin, and dipyridamole) versus heparin-warfarin, and dipyridamole for 2 years [186]. A decrease in proteinuria and mesangial deposition and a stabilization in number of sclerosed glomeruli was reported in the combination therapy group. The follow-up study revealed that 2 years of combination therapy improved the long-term outcome after 10 years [187] with better survival to the end point of eGFR<60 ml/min/1.73 m^2 (97% vs. 85% in anticoagulation arm). Another study enrolling patients with severe mesangial proliferation and comparing the effects of combination therapy vs. prednisolone alone showed additional benefits of the former [188]. However, side effects of prolonged anticoagulation and antiplatelet therapy have led to their discontinuation [189]. Azathioprine also needed frequent discontinuation, and mizoribine was used instead of azathioprine with improved tolerability [190]. In adults the addition of azathioprine to corticosteroids failed to prove further benefits and side effects were reported [191].

A recent retrospective study from Paris [192] examined children with severe clinical presentation and acute histologic features, who received therapy with either corticosteroids (sometimes in association with cyclophosphamide) and renin angiotensin axis blockers, or the latter alone. Although the baseline features were dissimilar for proteinuria and time from onset to treatment, a great benefit of corticosteroid/immunosuppressive therapy was reported, with improvement in eGFR and decrease in proteinuria after 6 months follow-up.

Mycophenolate Mofetil

Several small trials report conflicting results [193]. The KDIGO guideline does not recommend mycophenolate in IgAN, even though some benefits in Asian adult patients have been reported with a sparing effect on the total dose of corticosteroids [194]. A RCT that included children, young subjects, and adults examining the effects of corticosteroids, mycophenolate mofetil and fish oil was terminated after 6 months in view of failure to show any benefit [195].

Cyclophosphamide

This drug, in combination with corticosteroids, was tested in several uncontrolled case series. A small RCT [196] reported a protective effect of cyclophosphamide in progressive cases of adult IgAN. The STOP-IgAN study failed to show any benefits in patients with slightly reduced eGFR [177].

Rituximab

Because B cells may be involved in production of both Gd-IgA1 and anti-Gd-IgA1 antibodies, there is a rationale for considering anti-CD20 treatment in the condition. However, a small RCT of 34 patients that compared rituximab with supportive care failed to show an effect on eGFR, proteinuria, and Gd-IgA1 or anti-Gd-IgA1 antibody levels after 12 months [197].

Calcineurin Inhibitors

A recent meta-analysis reported limited effects of calcineurin inhibitors added to medium-low doses of prednisone and increased risk of adverse events [198].

Tonsillectomy

One of the first treatments considered for IgAN, particularly in children with recurrent gross hematuria, has been tonsillectomy. This procedure may theoretically eliminate pathogens which multiply in tonsils and remove macrophages and T cells, limiting Gd-IgA1 production. Several retrospective studies have analyzed the role of tonsillectomy in the treatment of IgAN mainly in adults [199]. Largely adopted in Japan, tonsillectomy in addition to steroid pulse was found in a RCT to provide a greater reduction in proteinuria in comparison to corticosteroids alone though the difference was marginal [200]. More recently a long-term follow-up reported a benefit on GFR decline in Japanese patients [199] and a meta-analysis concluded for some benefits in Japanese studies [201]. Tonsillectomy is indicated in children with IgAN when tonsils are a true infectious focus, or in case of recurrent tonsillitis (>3 episodes/year). In other cases the efficacy of the procedure has chiefly been reported from studies in Japan, and in association with other therapies.

Fish Oil/Omega 3 Fatty Acids

Data on efficacy of omega-3 fatty acids in children and adults with IgAN is limited, perhaps dose dependent, and not proven in a randomized study [185, 202]. KDIGO guidelines do not support this treatment in patients with IgAN.

Coagulation Modifying Agents

Warfarin, urokinase, and antiplatelet agents may add some benefits to corticosteroid treatment, but the side effects do not support their use in IgAN [187].

Future Therapies for IgAN

The enteric controlled-release formulation of the corticosteroid budesonide targets the Peyer patches at the ileocecal junction, which are pivotal for the GALT response [203]. Budesonide was tested in the placebo-controlled NEFIGAN phase 2b trial that showed a significant reduction of proteinuria and stabilization of eGFR over 9 months, without serious adverse events [204]. The drug is proposed to be tested in pediatric patients.

Combination of hydroxychloroquine and agents inhibiting the renin angiotensin axis showed significantly reduced proteinuria over 6 months in adults with IgAN [205].

New therapeutic approaches for IgAN include antagonists of the BAFF-TNF receptor family (BAFF, APRIL TACI). Trials with humanized monoclonal antibodies against these mediators are ongoing [38, 206]. Anticomplement drugs are under investigation for patients with IgAN, including anti-C5 (eculizumab), anti-C5a receptor inhibitors (CCX168), anti-C3 (compstatin), anti-factor D (lampalizumab), and MASP-2 inhibitors (OMS721) [38, 206].

Management of IgAN in Children

IgAN is no longer considered a benign disease and the diagnosis triggers the decision on need of treatment, choice of drug and duration [38]. No curative treatment is defined for IgAN: new studies target the pathogenetic events, including B cell and complement activation; however, results of these studies are not yet available [38, 206]. The identification of different risk levels at presentation, as recently offered to adult subjects with IgAN [112], should improve the selection of children to be treated and the choice of treatment [113]. A general approach to risk assessment, based on clinical and histological features, includes consideration of heavy proteinuria, mesangial proliferation, crescents, and glomerular sclerosis or interstitial lesions. Persistent proteinuria >0.5 g/day/1.73 m^2 is the most widely accepted indication for initiating treatment. However, lower levels of proteinuria (>0.3 g/day/1.73 m^2) might also be a risk factor over prolonged follow-up [207]. In children with acute onset, the variability in risk assessment due to timing of the biopsy [111] and the possibility of spontaneous improvement [165] limits the individual risk prediction at variance from adults, where a chronic and relentless progression is rather common [6]. Data from RCTs is scant and often inconclusive in children due to heterogeneity of risk factors and relatively short follow-up.

Hence, most data in children are derived from studies in adults, with the limitation of dealing with different expression of a same disease [6, 207]. A step forward to powered RCTs is to consider surrogate end-points in children as well as adults with IgAN, in order to shorten the observation time and increase the number of patients with better risk stratification. Proteinuria decrease is a widely accepted surrogate marker of reduced risk of progression [208]. Attention should be paid to conclusions from such surrogate markers, in absence of appropriate risk-matched control population.

Finally, there is a different attitude from clinicians in the selection of treatment for children and adults with IgAN: the choice in children with IgAN is often for a quick and powerful treatment, for fear of missing the active and reversible phase and not impair the subsequent sclerosis [6]. While we should refrain from treatments not based on evidence, the attempt to limit the progression of IgAN has to be individualized.

Selection of Patients

- Children with no risk for progression, for example, cases with isolated microscopic hematuria or gross hematuria completely resolved without any consistent persistent urinary abnormalities, should not receive treatment. Since the risk of progressive disease may change during the follow-up, regular re-evaluation is needed.
- A threshold value for considering treatment in children with persistent proteinuria, in addition to microscopic hematuria, is set at >0.5 g/g according to the KDIGO guidelines which recommend the use of ACE-I or ARB. Proteinuria values that exceed >0.3 g/day may be considered for this treatment.
- Children with clinical and pathology risk for progression should be offered 6 months corticosteroid treatment, either as IV pulses or as oral therapy. This group includes children with persistent proteinuria >0.5 g/g after 3–6 months RAS inhibition, or when values increase to >1 g/g in spite of RAS blockers or in cases with acute onset and worsening of renal function or active severe MEST-C scores. This choice remains opinion based, since no prediction formula integrating clinical and histological data suggesting specific treatment is presently available. The risk-benefit balance and steroid side-effects must be considered while making a decision regarding therapy.
- Children with nephrotic proteinuria associated with IgAN with minimal change disease features must be treated as those with minimal change disease alone.
- Children with acute kidney injury (AKI) in the context of macroscopic hematuria due to red blood cells and intra-tubular casts must follow the principles of supportive care for AKI.
- Cases with the rare variant of rapidly progressive glomerulonephritis and acutely decreased eGFR need to be treated as ANCA vasculitis, including the use of cyclophosphamide and steroid pulses. This protocol may be considered in patients with severe endocapillary hypercellularity or with crescent formation involving >30% of the glomeruli and a progressive course.
- The target of treatments is to reduce proteinuria <0.2 g/g. The follow-up must be continued in order to detect relapses that should be treated according to the new clinical features.

Abstract

IgA vasculitis, formerly known as Henoch-Schönlein purpura (HSP), is a clinical disorder defined as palpable purpura with one or more of arthritis/arthralgia, abdominal pain, renal involvement, or predominant IgA deposition. IgA vasculitis largely affects the pediatric population and generally has a favorable prognosis, with IgA vasculitis with nephritis being a feared outcome that contributes to poor prognosis. Renal involvement has a large range of symptoms, from microscopic hematuria to mixed nephritic-nephrotic syndrome with diminished renal function. The pathogenesis of IgA vasculitis with nephritis is similar to IgA nephropathy, suggesting a role of galactose-deficient IgA1 (GdIgA1) acting as an autoantigen, resulting in immune complex formation and deposition within the kidneys. Histology is indistinguishable between IgA vasculitis with nephritis and IgA nephropathy, with crescents and mesangial hypercellularity being hallmark features of IgA vasculitis with nephritis. Treatment recommendations are aimed at treatment of proteinuria when present, as well as attempting to reduce nephritis to prevent long-term damage by treatment with corticosteroids and immunosuppressive medications. Studies are currently ongoing to review clinical and histological factors that may suggest poor prognosis, with degree of proteinuria an important marker for outcome. Children with a history of IgA vasculitis with nephritis require long-term monitoring for adverse outcomes including hypertension, CKD, and ESKD.

Introduction

IgA vasculitis, formerly known as Henoch-Schönlein purpura (HSP), is a multisystem disorder that predominantly affects the skin, joints, gastrointestinal tract, and kidneys [1–5]. The diagnostic criteria for IgA vasculitis are presented in Table 1 [6]. The name and recognized elements of this condition have evolved. In 1801, Heberden reported a 5-year-old boy with abdominal pain, vomiting, melena, joint pain, petechial hemorrhages on his legs, and urine “tinged with blood.”

Table 1 Diagnostic criteria for IgA Vasculitis [6, 9]

Palpable purpura (mandatory criterion)
And one or more of the following:
Arthritis or arthralgia
Diffuse abdominal pain
Renal involvement (hematuria and/or proteinuria)
Leukocytoclastic vasculitis with predominant IgA deposit of proliferative glomerulonephritis with predominant IgA deposits

In 1837, Schönlein first described the condition in which arthralgia was associated with purpura. In 1868, Henoch described the gastrointestinal manifestations of purpura rheumatica, and 30 years later, he referred to nephritis as a complication. Other references to IgA vasculitis in early publications have used the terms of anaphylactoid purpura, purpura rhumatoide, and Schönlein-Henoch syndrome [7, 8]. The contemporary diagnostic term *IgA vasculitis* will be used in this chapter [5].

Epidemiology

IgA vasculitis (IgAV) occurs mainly in children, but adults can be affected [10]. While 90% of cases occur before 10 years of age, IgA vasculitis is rare among children younger than 2 years, peaks between ages 4 and 6 years, and has a declining incidence in adolescents and adults [11]. There is slight male predominance of 1.5:1 in children [12, 13]. The annual incidence is estimated at 3 to 27 pediatric cases per 100,000 children [11, 13–17] and 0.8 to 1.8 cases per 100,000 adults [10, 18–20]. The wide range in incidence in childhood appears to represent geographic variability, with incidence being reported as high as 55.9 children per 100,000 cases in Korea [21].

Though IgA vasculitis is the most common vasculitis in children, it generally has a good prognosis with the majority of children experiencing resolution of signs and symptoms. A study in the United States found hospitalization of children diagnosed with IgA vasculitis to be 2.4 per 100,000 pediatric population per year between 2006 and 2014 [22]. There is significant seasonal variation in disease presentation for children, with the peak incidence occurring during the fall and winter [11, 15, 16, 19, 23, 24]. There does not seem to be a similar seasonal variation for adult cases [10]. IgA vasculitis has a wide geographic distribution with appreciable variation. Clinical reports based on large patient numbers have originated mostly from Europe [14, 23, 25, 26], Finland [27, 28], and Asia [21, 29]. The condition appears to be less common in North America and Africa, but this may represent a reporting bias. Differences in disease risk have been postulated based on environment and ancestry, because IgA vasculitis is rare among African Americans in the southern United States [30, 31] and among persons from the Indian subcontinent [32]. In the West Midlands of England, white and Asian children had an incidence three to four times greater than black children [33]. No single infectious agent has been associated with IgA vasculitis, but observations suggest that 30–65% of IgA vasculitis cases are associated with viral or bacterial upper respiratory infections [34].

The proportion of IgA vasculitis patients with renal involvement ranges from 20% to 55% [35–37]. These variations may depend on the presence or absence of systematic urinalysis screening in IgA vasculitis cases, ambulatory or hospitalized sources of cases, and the location of care inclusive or exclusive of centers with nephrology expertise. Two studies in which routine urinalysis was performed for all patients admitted to the hospital for IgA vasculitis showed renal involvement in 41% and 61% of cases, respectively [38, 39].

Mechanisms of Disease

IgA vasculitis with nephritis (IgAVN) in children is usually an acute disorder with an abrupt onset [40]. The most accredited pathogenic hypothesis to date does not discriminate between IgA vasculitis and IgA nephropathy (IgAN), or the genetic background of these disorders. However, IgA vasculitis is distinguished by the degree of the systemic inflammatory response. A variety of stimuli ranging from infections by almost all types of pathogens, drugs, and allergens has been postulated to contribute to initiation of IgA vasculitis.

The multistep pathogenetic model for both IgA vasculitis with nephritis as well as IgA nephropathy begins with the synthesis of galactose-deficient IgA (Gd-IgA1). Gd-IaA1 behaves as an autoantigen and elicits production of autoantibodies of IgG or IgA class. IgG-Gd-IgA1 forms circulating immune complexes, which subsequently deposit in the mesangium. Upon immune complex deposition, mesangial cells react with multiple activation signals, inciting the release of cytokines and chemokines and amplifying the inflammatory response (Fig. 1) [41].

Role of Genetic Conditioning

The genetic predisposing background has been attributed to human leukocyte antigens (HLA) class I and class II genes [42]. In populations of European origin, HLA-class II DRB1 haplotype (HLA-DR1*0103 allele) and HLA class I B35 have been associated with susceptibility to the disease and to kidney involvement [43, 44].

Several polymorphisms or genetic variants within certain loci of non-HLA genes involved with autoimmune diseases or vasculitis and almost every gene encoding cytokines and chemokine involved with endothelial activation, adhesion, and inflammation have been explored [42, 45]. Among these, variants of genes encoding for interleukin 18 (IL-18), transforming growth factor beta1 (TGFB1), monocyte chemoattractant protein 1 (MCP1), selectin P (SELP), and Mediterranean fever – Pyrin (MEFV) were found to influence susceptibility to the disease. Variants in genes encoding for interleukin 1 beta (IL-1ß), interleukin 1 receptor antagonist (IL-1ra), TGFB1, interleukin 8 (IL-8), chemokine (C-C motif) ligand 5 (CCL5), and cytotoxic T-lymphocyte antigen 4 (CTLA4) influenced the occurrence and severity of renal damage. Variants in *MCP1*, intercellular adhesion molecule 1 (*ICAM1*), angiotensin, and *MEFV* seem to be involved in favoring gastrointestinal localization of disease manifestations. Endothelial genes involved in vascular reactivity, including nitric oxide synthase (NOS), renin angiotensin system (RAS), and the coagulation cascade, are possibly involved in the vasculitic process [46–50].

The abnormally galactosylated IgA (Gd-IgA) drove attention to the gene encoding β1-3 galactosyl transferase (GALT), and its chaperone core (1β3-Gal-T-specific molecular chaperone, COSMC) as determinants of glycosylation of IgA molecules [48, 51], especially since Gd-IgA are also observed in healthy relatives of the patients [52]. Most studies did not find significant difference in serum Gd-IgA between IgA vasculitis and IgA nephropathy. Aberrant glycosylation compared to the healthy

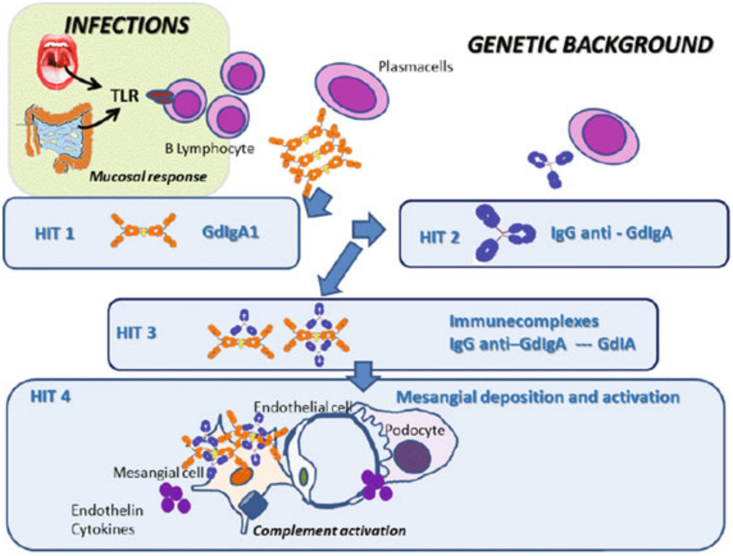

Fig. 1 Multistep pathogenetic model of IgA vasculitis with nephritis. TLR Toll-like receptor; Gd-IgA galactose-deficient IgA; IgG-Gd-IgA Immunoglobulin G galactose-deficient IgA antibody-antigen complex

population was confirmed. Antibodies at high titer against Gd-IgA are associated with most active cases of IgA vasculitis with nephritis in childhood [53].

Pathogenesis and Mechanisms of Disease Progression

IgA vasculitis with nephritis is characterized by inflammatory mechanisms in endothelial cells as well as mesangial cells, causing a strong vascular involvement both in the kidney and in other organs. The development of vasculitis is partially understood.

The endothelial cell is highly reactive and susceptible to cascades of complement, coagulation, and inflammation. One hypothesis is that IgA is generated from a cross reaction or molecular mimicry between the endothelial membrane molecules and the antigens expressed by the multiple pathogens colonizing the upper airways or the intestinal mucosae. These IgA molecules are directed against endothelial cells and induce vasculitis [54, 55]. Gd-IgA expose uncovered N-acetyl galactosamine (GalNAc) due to lack of the terminal Gal residue in the side glycidic chain of the IgA molecule. GalNac exposure is a common characteristic of the membrane of many pathogens and is therefore the appropriate self-reaction against Gd-IgA, being the second hit of the pathogenic chain [56]. IgA1 can bind to β2 glycoprotein, bridging IgA to phospholipids on the endothelial cell membrane [57], thus favoring amplification of thrombus formation and vasculitic damage. IgA1 binding to endothelial cells is enhanced by cytokines released during infections, such as tumor necrosis factor-α (TNF-α). Once bound to endothelial cells, IgA1 can bind to Fc receptor α expressed by circulating inflammatory cells, such as neutrophils favoring their adhesion to the endothelium and further attracting other inflammatory cells upon chemokines and complement fractions with chemotactic activity [58]. Upon IgA binding to endothelial cells via specific antigen recognition or via nonspecific binding via FcR α, a bridge is created attracting circulating cells to the vessel wall, amplifying the vasculitis through leukotriene and other endothelial products massively attracting neutrophil migration to the injured endothelium. Neutrophils release reactive oxygen species while bound IgA1 proceeds to activate the complement cascade resulting in endothelial cell lysis, necrosis, and formation of microthrombi.

Complement activation in IgA vasculitis with nephritis is recognized as one of the key pathogenic components. The classical, alternative, and lectin pathways can be triggered and activate the C3 and C5 convertases, resulting in the formation of the full membrane attack complex. In serum and on kidney biopsies, C3d, C4d, C5b-9, mannose-binding lectin (MBL), and mannose-associated serine protease 1 (MASP-1) staining have been observed [59]. C4d staining in the glomeruli and in the arterioles is frequently found in IgA vasculitis with nephritis and in active IgA nephropathy [60] and colocalized with microangiopathic lesions [61]. The coagulation system is more frequently engaged in IgA vasculitis with nephritis, compared to IgA nephropathy, with reduced serum factor XIII levels and increased expression of lipoprotein A (LPA), thrombomodulin, plasminogen activating factor (PAI-1), and S and C proteins [62].

The role of endothelial cells in the pathogenesis of rapidly progressive and acutely inflammatory forms of IgA nephropathy was valued in the Oxford classification that assigns a score to endothelial cell activation and damage. Endocapillary hypercellularity, E1, in the original cohort and in the other confirmative validation studies proved predictive of unfavorable outcome on univariate analysis in adults [63] and was an independent predictor of worse outcome with multivariable analysis.

The predictive value of endocapillary hypercellularity on outcome was stronger in IgA vasculitis with nephritis than in primary IgA nephropathy [64], though it is difficult to extrapolate the role of treatment in retrospective series. A large review of kidney biopsies in IgA vasculitis with nephritis is underway to determine morphological lesions of prognostic significance. Additional long-term follow-up studies are needed to validate the value of endocapillary hypercellularity or other lesions as prognostic indicators in children with IgA vasculitis [65].

Clinical Features

The extrarenal manifestations of IgA vasculitis are characteristic and can occur in any order across several days or weeks. The skin lesion typically begins with erythematous macules, some of which develop into slightly raised (palpable), urticarial papules. These early lesions may become purpuric (Fig. 2). The eruption is of symmetric distribution and predominantly affects the buttocks and the extensor surfaces of the lower legs and forearms but spares the trunk [12, 66, 67]. Purpura occasionally affects the ear lobes, nose, and external genitalia but in mild cases may be confined to the ankles. Among older children, purpura may be the sole cutaneous manifestation. As the primary lesions fade, new crops of purpura may recur 3 months after onset and occasionally much later [23, 25]. Cutaneous recurrence may be accompanied by the recurrence of abdominal, joint, and renal manifestations. A skin biopsy will demonstrate the presence of IgA deposits in small vessels, if needed to confirm the diagnosis [6, 12].

Joint symptoms are rarely the initial manifestation of IgA vasculitis, but ultimately occur in approximately 60 to 90% of children [12, 23, 25, 28, 69]. The spectrum of joint manifestations of IgA vasculitis consists of arthralgia, arthritis, and periarticular edema without overlying erythema, tenderness, or joint effusions. Joint involvement affects the lower extremities more commonly than the upper extremities [12, 28]. These symptoms are transient and leave no residual damage.

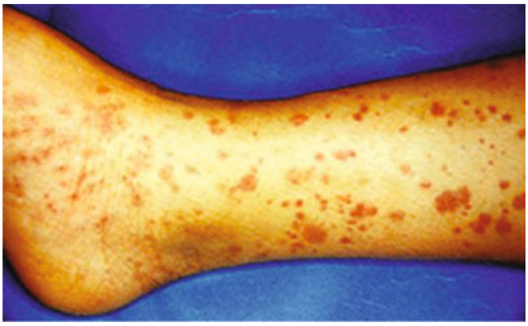

Fig. 2 Palpable purpura in a patient with IgA vasculitis [68]

Gastrointestinal manifestations are the presenting manifestation in 10–40% of cases and occur in 50–70% of children with IgA vasculitis [28, 70]. The incidence of gastrointestinal involvement increases the likelihood of renal involvement [23, 25, 66, 71]. The most common symptom is abdominal colic due to bowel angina [12], which often is severe and accompanied by vomiting. Melena occurs in one-half of cases [70]. As many as 22% of patients had occult blood in the stool, when GI manifestations were thought to have been evaded [28]. When the abdominal symptoms precede the other manifestations, laparotomy is sometimes considered necessary [25]. Intussusception due to severe purpura of the intestine is uncommon and mostly isolated to the small bowel [21, 72–74]. Protein-losing enteropathy has been reported [28, 75, 76] and may account for the occasional observation of hypoalbuminemic edema in the absence of heavy proteinuria. Rarely, abdominal colic may be attributed to ureteritis, resulting in obstruction of the ureter due to inflammation [77].Though uncommon, head imaging studies performed on patients diagnosed with IgA vasculitis and found to have altered mental status or focal neurologic lesions have identified intracranial hemorrhage, brain edema, and thrombosis of the superior sagittal sinus [78]. Vasculitic lesions have been found in many other organs and may explain rare manifestations such as pulmonary hemorrhage, acute hemorrhagic pancreatitis or parotitis, testicular hemorrhage, orchiditis, and myocardial or muscle involvement [28, 70, 77–80].

Renal manifestations occur at any time, with an incidence of ~25 to 50% [28, 35, 37, 69, 81, 82]. Renal manifestations may be minor, including microscopic hematuria or subnephrotic range proteinuria, or can be severe, including diminished eGFR, nephrotic syndrome, nephritic syndrome, or a mixed nephritic-nephrotic syndrome picture. The first urinary abnormality is usually noticed after other symptoms manifest. Among 80% of children that develop kidney involvement, the first abnormality is detected within 4 weeks of onset of IgA vasculitis. In most of the remainder, the urinary abnormality develops within the next 8 weeks [23].

A study of 238 children with IgA vasculitis showed that most patients (91.0%, 95% CI 85.0%–97.0%) developed abnormal urinalysis within the first 6 months [83]. The most common clinical manifestation was isolated microscopic hematuria or sub-nephrotic proteinuria in about 60% of the cases. Severe nephrotic proteinuria with kidney failure was identified in 30% cases. In a smaller proportion, ~20% cases, a rapidly progressive glomerulonephritis occurred, advancing to kidney failure in less than 10% of patients in the last 20 years. These outcomes were assessed during a period when widely diffuse immunosuppressive treatment was used with a goal to ameliorate the long-term risk for kidney failure [84–86].

Recurrences of renal manifestations are common and appear to be particularly so among patients with severe renal damage and older age at diagnosis. The relapses can occur at the time of an upper respiratory tract infection. There are no correlations between the severity of extrarenal and the renal symptoms. There seems to be no association between treatment with prednisone and prevention of recurrence of disease [28].

Several studies have been conducted to identify predictive factors for renal involvement in childhood IgA vasculitis [37, 87–92]. These studies show that age greater than 8 years at onset, persistent purpura, severe bowel angina, and relapse were identified as factors associated with the occurrence of renal involvement. This study also showed that patients with two or three risk factors developed nephritis in 63% and 87% of cases, respectively [93]. Minimal renal involvement may cause no more than transient microscopic hematuria, detectable only on routine urinalysis during the acute illness. The nephritis of IgA vasculitis may also present with macroscopic hematuria that usually lasts a few days. Macroscopic hematuria may persist for several weeks and microscopic hematuria may persist for many years. Macroscopic hematuria may be accompanied by transient heavy proteinuria. Persistence of heavy proteinuria of more than 1 g/m^2/day with microscopic hematuria is associated with significant histologic lesions, including crescents, endocapillary hypercellularity, and tubulointerstitial injury [94, 95].

Impairment of kidney function is uncommon and occurs with acute nephritic syndrome associated with combination of hypervolemia, oliguria, and hypertension [25]. Massive proteinuria can cause nephrotic syndrome (albumin <25 g/l) with pitting edema of the face and ankles and sometimes ascites. The most severe clinical presentation is mixed nephritic-nephrotic syndrome in which hematuria, hypertension, and impaired kidney function are combined with proteinuria and hypoalbuminemic edema [25]. Such a presentation is most often associated with crescentic glomerulonephritis or segmental glomerulosclerosis.

Pathology

The renal histopathology of IgA vasculitis is indistinguishable from that of IgA nephropathy; however, two basic types of glomerular lesions are the hallmark of IgA vasculitis with nephritis: mesangial hypercellularity and crescents.

Light Microscopy

Mesangial damage is the main feature and is characterized by variable hypercellularity, ranging from isolated mesangial hypercellularity to focal and segmental endocapillary hypercellularity with various extent of crescent formation. Figure 3 highlights endocapillary hypercellularity on light microscopy. Adhesions of the tuft to the Bowman capsule can be coincident with lesions of segmental hypercellularity, often with double contour appearance of glomerular basement membranes (GBM). A membranoproliferative pattern of injury may also rarely be present, due to mesangial cells and/or infiltrating macrophages/inflammatory mononuclear cells interposing themselves in the capillary loops between the endothelium and the GBM in response to subendothelial deposits. The ensuing matrix reaction, along with the interposed cells and deposits, gives

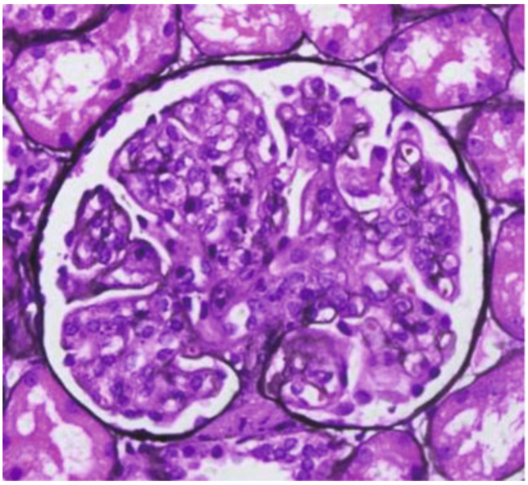

Fig. 3 Global endocapillary hypercellularity in a biopsy of IgA vasculitis (Jones silver stain, original magnification x 400)

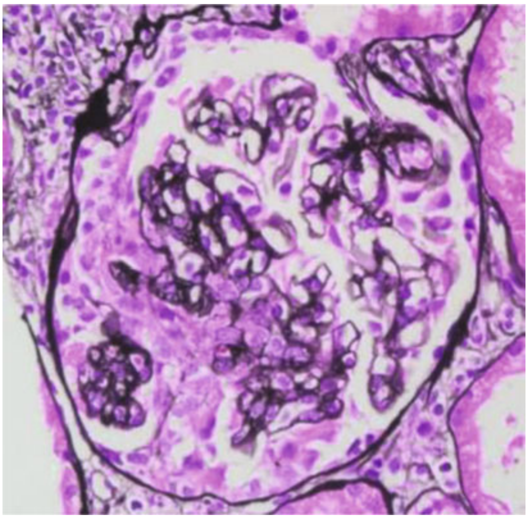

Fig. 4 Cellular crescent in IgA vasculitis in conjunction with segmental endocapillary hypercellularity, lower left (Jones silver stain, original magnification x 400)

rise to the double contour of the GBM observed on silver stain that stains only the matrix. Endocapillary hypercellularity occurs due to an increased number of cells within the glomerular capillaries causing narrowing of lumina. It may be focal or diffuse, and segmental or global, and is associated with extension of the deposits to the subendothelial location of peripheral loops. Hypercellularity may be attributed to inflammatory cell infiltration and endothelial cell swelling and/or proliferation. Endocapillary lesions are more common in children than adults and are associated with active disease. Crescents vary in size, from segmental to circumferential, evolve from cellular to fibrocellular to fibrous, and finally assume sclerotic aspects, with segmental or global scars. In mild cases, the crescents are small and limited to a small percentage of glomeruli, generally lower than 50% in association to endocapillary focal or diffuse hypercellularity [96–99]. Severe crescents, that involve more than 50% glomeruli, are seen in ~25% of the cases. Crescentic glomerulonephritis is most likely overrepresented, since patients with milder illness do not as often undergo biopsy. Figure 4 shows crescent formation with endocapillary hypercellularity.

Other lesions present in a minority of children are accumulation of fibrinoid material and necrosis of the tuft with inflammatory infiltration typical of vasculitis. Usually necrotic lesions are associated with diffuse crescents and acute inflammation. Tubular lesions are rarely observed in the acute phase, although acute tubular injury with flattening, vacuolization, desquamation, and focal loss of the brush-border microvilli may be seen. Tubular cylinders and blood casts are detected in 30% patients. When biopsy is delayed to over 6 months from the clinical onset, tubular atrophy with interstitial fibrosis and interstitial lymphocyte infiltration in areas of scarring are frequent, as seen in adults with IgA vasculitis. A small number of globally sclerosed glomeruli are often present. The membranoproliferative lesion described above may also more commonly be seen in the later stage biopsies.

Immunofluorescence

IgA vasculitis by immunofluorescence or immunohistochemistry is almost indistinguishable from IgA nephropathy. The diagnostic immunopathology feature is the presence of diffuse and usually global dominant or codominant IgA granular deposits in the mesangium. IgA deposits often may extend beyond the mesangiocapillary junctions into the adjacent capillary walls, and in some cases to peripheral capillary walls, most often associated with more hypercellularity (Fig. 5). Deposits of IgG and/or IgM with the same staining pattern of IgA are frequently present, and most often are of less intensity. IgA1 is the dominant subclass with polyclonal staining, often with slightly more lambda than kappa, in contrast to other immune complex disease where kappa is slightly more abundant than lambda. This is postulated to reflect the mucosal origin of the IgA deposits in IgA nephropathy and IgA vasculitis with nephritis, contrasting the bone marrow origin of the plasma cells giving rise to other immune complexes. The J chain is detectable, indicating that IgA in deposits is dimeric. The secretory component, synthesized by the epithelial cell to allow the trancytosis process across the epithelial cells, is absent. Extensive subendothelial deposits are associated with the most severe histologic forms with endocapillary hypercellularity and even crescents. C3 deposits are present in the majority, while the early fraction of complement cascade C4 and C1q is rarely present. C5–C9 and the alternative complement pathway component are instead always detectable. Fibrin or fibrinogen fractions are found with diffuse distribution in 25–70% patients, both in mesangial and parietal areas and coincident with mesangial hypercellularity, suggesting activation of the clotting cascade, particularly in cases with a high inflammatory status.

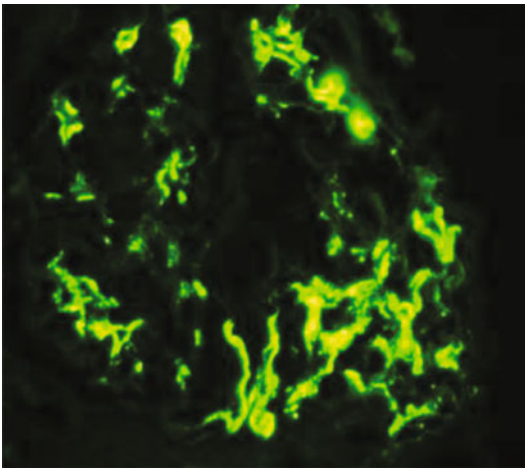

Fig. 5 IgA dominant staining in IgA vasculitis, with dominant mesangial staining with segmental capillary loop extension at lower right (anti-IgA immunofluorescence, original magnification x 400)

Electron Microscopy

The mesangium is variably expanded by a combination of increased cells, matrix, and deposits. Electron-dense deposits in the mesangium are present in almost all patients, but may be less conspicuous than expected from immunofluorescence findings (Fig. 6). The deposits have a granular aspect and are situated beneath the lamina densa, in the perimesangial region and in the expanded mesangium. The size is variable from very small to large and protruding. Peripheral glomerular capillary wall deposits are present mainly in the subendothelial areas and less frequently in the subepithelial areas in the capillaries adjacent to the mesangium, although also observed in the peripheral part of the loop. Frequent subepithelial or hump-type deposits should arouse suspicion for possible IgA dominant infection-related glomerulonephritis, particularly if there is a dominant glomerular neutrophil infiltrate with strong C3 staining. Clinical assessment and integration of all findings should allow distinction of these possibilities. The epithelial foot processes are well preserved; extensive foot process effacement may be seen in patients with nephrotic syndrome.

Comparison of IgA Vasculitis with Nephritis with IgA Nephropathy

IgA Vasculitis with nephritis may have a higher degree of likelihood for severe and acute pathology manifestations. Severe mesangial hypercellularity may progress to cellular interposition, inflammatory cells, and occasional mesangial cells interposing themselves into the capillary walls between the basement membrane and endothelial cytoplasm, typically in response to subendothelial deposits. The resulting basement membrane gives the capillary walls a “double contour” on silver staining, as detailed above. This membranoproliferative pattern of injury is

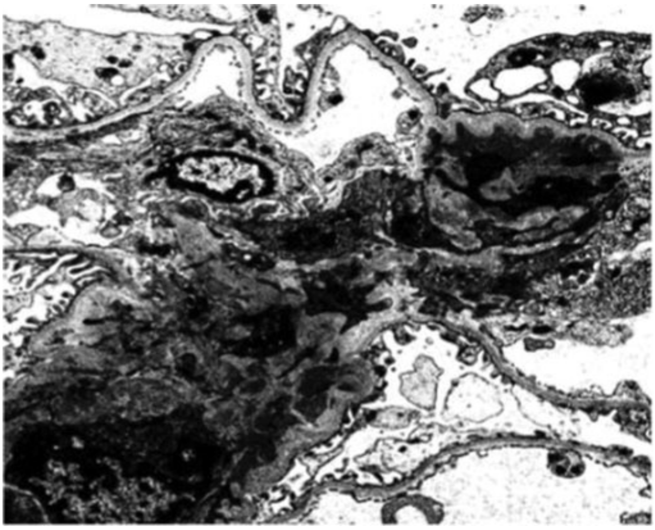

Fig. 6 Electron micrograph showing electron-dense deposits in the mesangium in a patient with IgA nephropathy [68]

only rarely diffuse. IgA vasculitis with nephritis compared to IgA nephropathy may have a greater degree of crescents. Endothelial activation typical of vasculitis leads to coagulation and complement cascade trigger, amplifying the endothelial damage and resulting in tuft necrosis. The released tissue factor, coagulation fractions, and fibrinolytic enzymes damage the GBM and infiltration of inflammatory cells. Release of these mediators, after GBM break, into the Bowman space stimulates the proliferation of parietal epithelial cells and influx of inflammatory cells, resulting in a crescent. Crescents reflect an extremely active, acute inflammatory process, often in parallel with clinical manifestations characterized by acute nephritic syndrome, rapidly progressive glomerulonephritis, hypertension, and gross hematuria.

Timing of Biopsy and Histology Findings

The presence of crescents is strongly dependent upon timing of kidney biopsy. Crescents may regress or evolve to sclerotic lesions when the kidney biopsy is postponed for months [100]. A recent large German collaborative study clearly demonstrated how timing of biopsy in children with IgA vasculitis with nephritis is crucial for the histological findings [97]. Cellular crescents were present in high percentage in early biopsies, within 15 days from clinical onset, while absent or partly evolved to fibrous crescents in late biopsies. The cases with a less abrupt clinical onset and milder renal symptoms may risk underestimation of the small percentage of crescents, depending on the timing of the biopsy and the adequacy of the biopsy specimen.

Histological Classifications and Their Significance

Three histological classifications have been developed. The inclusion of mesangial hypercellularity and crescent evaluation and quantification is common across the classifications and inclusion of acuity and chronicity elements varies. The generation of a classification measure inclusive of chronicity indices was in response to the low predictive value of long-term outcomes based exclusively on acute lesions in IgA vasculitis with nephritis [101].

ISKDC

This classification, developed by pathologists of the International Study of Kidney Disease in Children (ISKDC), is based on the degree of mesangial hypercellularity and proportion of glomerular crescents. ISKDC classes I–II include biopsies without crescents, while classes III, IV,

Table 2 ISKDC Classification [102] (Ref. [121])

I	Minimal glomerular abnormalities	
II	Pure mesangial proliferation	Focal or diffuse
III	Minor glomerular abnormalities or mesangial proliferation, with crescents or segmental lesions (sclerosis, adhesions, thrombosis, necrosis) in fewer than 50% of glomeruli	Focal or diffuse mesangial proliferation
IV	As III but with crescents or segmental lesions in 50–75% of glomeruli	Focal or diffuse mesangial proliferation
V	As III but with crescents or segmental lesions in more than 75% of glomeruli	Focal or diffuse mesangial proliferation
VI	Membranoproliferative- like lesion	Focal or diffuse mesangial proliferation

and V are defined by percent glomeruli with crescents categorized as <50%, 50–75%, or > 75%, respectively (Table 2) [102].

MEST

The Oxford MEST classification was designed for primary IgA nephropathy and considers mesangial hypercellularity, endothelial hypercellularity, segmental glomerulosclerosis, and tubular atrophy-interstitial fibrosis [103]. Crescents (cellular or fibrocellular; fibrous crescents are not scored) are scored as absent (C0), <25% (C1) or ≥25% C2 [104]. The MEST-C classification started to be used in children and adults with IgA vasculitis with nephritis to overcome the low predictive value of ISKDC. Validation initiatives require additional data and longitudinal assessments to assess the value of the MEST-C for children and adults with IgA vasculitis are underway. To date, distinct components of the MEST-C have been evaluated in small cohorts. M1 and S1 scores are reported to be more reliable in pediatric studies more frequently than in adults, while E1 and T1-2 scores have been useful in small cohorts of all ages [105]. Additionally, mesangial hypercellularity, segmental sclerosis, and tubular atrophy-interstitial fibrosis have been identified as prognostic for poor renal outcome. Segmental sclerosis on biopsy was associated with poor renal outcome (defined as 30% decrease in baseline eGFR, doubling of serum creatinine, or ESRD), with a hazard ratio 4.1 (CI 1.1, 15.0) compared with biopsies that did not have this finding [29]. Mesangial hypercellularity in greater than 50% of glomeruli (M1) and tubular atrophy-interstitial fibrosis of 25% or more of the biopsy (T1/T2) are prognostic of kidney failure (doubling of creatinine or ESKD) with hazard ratio of 4.0 (CI 1.2, 13.3) and 12.2 (CI 2.7, 55.3), respectively [105]. The predictive value of crescents (C0, C1, and C2) was confirmed in small adult cohorts, but not at multivariable analysis, which failed to show that crescents, the most impressive histologic feature of IgA vasculitis with nephritis, had a strong long-term predictive value for progression to kidney failure. Studies reviewing biopsies showing crescentic nephritis were found to have an odds ratio 3.9 (CI 2.4, 6.3) of developing poor renal outcomes, defined as hypertension, proteinuria >40 mg/m^2/h, increased serum creatinine, uremia, ESKD, dialysis, or transplantation [26, 29, 35, 105–108]. These studies are limited by their retrospective nature and varied treatments. Thus, C1 was associated with worse prognosis in IgA nephropathy only if no immunosuppression was given, while C2 lesions were associated with worse outcome regardless of immunosuppression [109–112].

Other Classifications

The low predictive value of histological lesions in IgA vasculitis with nephritis scored using different classifications leads to additional pathology grading efforts [113], mainly stemming from the original ISKDC or the MEST-C approaches. Among these, a recent work in a Finnish cohort of 53 children introduced a semi-quantitative description of lesions [114]. In this classification, a score was attributed to 14 parameters, crescents were distinguished as cellular or fibrous, and the different parameters were then combined into activity or chronicity indices. The performance of this classification awaits validation in larger independent cohorts. The low predictive value of crescents and the better performance of chronicity indices have been demonstrated in several other studies. In particular, sclerosis and interstitial fibrosis/tubular atrophy lesions over a 10-year follow-up are stronger negative predictors than crescents [65]. The absence of chronicity lesions, in particular if associated with low to normal excretion of urine protein, is considered predictors of better long-term kidney survival.

The predictive value of histology is low for IgA vasculitis with nephritis, in particular when classifications based on only acute lesions and crescents are used. This concept has been recently reminded in work that showed that low grade histology with mild smoldering proteinuria, receiving short term or no treatment may have worse long-term outcome than severe cases, aggressively treated to clinical and laboratory remission [115, 116].

Laboratory Investigations

IgA vasculitis is a diagnosis of exclusion, with no specific serum or urine findings. Of all pathogens linked to IgA vasculitis, group A β-hemolytic streptococcus is the most studied. Titers to anti-streptolysin O are raised in 20–50% of patients [117]. Further laboratory investigation is needed and has so far mainly been directed at assessment of the extent of renal involvement. If purpura is absent but is suggested by the patient's recent history, feces should be tested for occult blood, the finding of which may support a diagnosis of IgA vasculitis. If there is any doubt about the cause of purpura, a complete blood cell count and coagulation screen are performed. The level of clotting factor XIII, a fibrin stabilizing factor, is markedly low among children with IgA vasculitis. Although the serum IgA level is high in some cases of IgA vasculitis, measuring IgA levels for individual patients does not contribute to management.

In every case of IgA vasculitis, the urine is routinely tested for blood and protein at onset and at least weekly until systemic signs have resolved. A systematic review recommends that urine testing should be continued for 6 months, even if urinalysis is normal at presentation [118]. If urinary abnormalities are found, proteinuria is quantified, and serum levels of total protein and albumin are measured. Serum creatinine level is measured to estimate the eGFR.

Clinicopathologic Correlation

Renal biopsy is rarely needed for diagnosis, but it is used to assess the severity of glomerulonephritis [119]. Biopsy is required only in the care of patients with severe initial manifestations (nephritic, nephrotic, or decreased renal function) or with heavy proteinuria, for example, >1 g/day/m^2 that persists longer than 1 month. Biopsy for slight proteinuria, for example, <1 g/day/m^2, that persists longer than 3 months may be considered. The more severe the clinical presentation, the larger is the percentage of glomeruli affected by crescents and other hypercellular and/or sclerosing segmental lesions. The current clinicopathologic correlations in IgA vasculitis with nephritis aligned with contemporary pathology classification schemes are not well defined. However, a low activity and chronicity score portends excellent long term kidney survival, and high grade activity and chronicity might lead to a comparatively greater long-term risk for kidney failure [25, 86, 120–122].

Differential Diagnosis

IgA vasculitis is one of the small vessel vasculitides. The definition of the childhood vasculitides is based on the International Consensus Conference Nomenclature of Vasculitides (CHCC2012) [123, 124]. The distribution of the rash and the accompanying gastrointestinal and articular lesions are characteristic and, when combined with laboratory studies that exclude other small vessel vasculitis, the diagnosis is made [9, 119, 125]. Differential diagnoses of IgA vasculitis include other causes of purpura. Thrombocytopenic purpura and other vasculitides, such as hypersensitivity vasculitis, urticarial vasculitis, cryoglobulinemic vasculitis, cutaneous polyangiitis nodosa, and ANCA-associated vasculitis, must be differentiated. Difficulty arises in rare instances when the skin eruption consists entirely of urticarial lesions without purpura. Although it is not feasible to diagnose IgA vasculitis in the absence of cutaneous manifestations, there is anecdotal evidence that IgA vasculitis occurs without skin lesions, albeit rarely [126].

Among older children and adults, the combination of joint symptoms and purpura makes it necessary to consider systemic lupus erythematosus and microscopic polyangiitis as alternative diagnoses [127]. The light microscopic findings of glomeruli in patients with systemic lupus erythematosus and those with IgA vasculitis with nephritis are similar and may be indistinguishable. In systemic lupus erythematosus, however, glomerular IgA deposits, when present, are less prominent than IgG deposits, and C1q deposits are almost always present. Antinuclear antibodies usually are absent from patients with IgA vasculitis with nephritis. The differentiation between IgA vasculitis with nephritis and microscopic polyangiitis relies on antineutrophil cytoplasmic autoantibody titers (ANCA), for example, MPO and PR3, as well as the kidney biopsy. ANCA titers are typically elevated in microscopic polyangiitis and mesangial IgA, or any type of deposits, are absent or very sparse (pauciimmune necrotizing crescentic glomerulonephritis) [128].

Relationship Between IgA Nephropathy and IgA Vasculitis

The relation between IgA nephropathy and IgA vasculitis is complex, and there seems to be a close relationship [129]. The morphologic and immunopathologic features are similar in the two conditions [128, 129]. Serum levels of IgA are elevated in both IgA nephropathy and IgA vasculitis, and IgA-containing circulating immune complexes have been found in both conditions. The two disorders have been reported to coexist in different members of the same family, including a pair of monozygotic twins who developed the disorders simultaneously after a well-documented adenovirus infection [3, 31, 130, 131]. Moreover, the evolution of IgA vasculitis into IgA nephropathy in the same patient is described in both adults and children [132–134]. It has been suggested that the two conditions are variants of the same process and that IgA nephropathy is IgA vasculitis with nephritis without the rash [128, 131, 134]. Although there are similarities in their pathologic and immunologic features, the two conditions are clinically different. IgA vasculitis with nephritis tends to be an acute disease, with glomerular lesions that do not progress after disease onset [100, 120]. Therefore, in most patients, the prognosis is associated with the severity of glomerular change at the onset. In contrast, IgA nephropathy is a chronic, slowly progressive glomerular lesion, which may eventually lead to end stage kidney disease. A few patients with IgA vasculitis with nephritis have recurrent episodes of macroscopic hematuria and progressive kidney disease on repeat biopsies. Finally, IgA vasculitis with nephritis occurs mostly in young children and is rare in adulthood, whereas IgA nephropathy affects mainly older children and young adults [135]. It is therefore reasonable that IgA nephropathy and IgA vasculitis with nephritis be treated as different entities until their pathogeneses are better understood.

Treatment

Prevention of Nephritis

Steroids are effective in accelerating and favoring the resolution of arthritis and abdominal pain in IgA vasculitis; however, their effectiveness in the prevention of nephritis has been debated for decades. The fear of an unfavorable long-term renal outcome [99] prompted pediatricians to attempt preemptive treatment aimed at avoiding the occurrence of nephritis, mainly with oral steroids in short-term courses. The KDIGO 2012 guidelines included 5 RCTs with 789 children, where no protection on the development of persistent kidney involvement (microscopic hematuria, proteinuria, hypertension, reduced kidney function) at 6 and 12 months was obtained by 2–4 weeks of oral steroids. The KDIGO thus does not recommend the use of corticosteroids to prevent IgA vasculitis with nephritis (grade 1B) [136]. A recent placebo-controlled trial [137] also showed no evidence that systemic therapy with corticosteroids was associated with reduced occurrence of nephritis [138].

Treatment Options

The difficulty in determining therapy for IgA vasculitis with nephritis is small patient numbers with inability to evaluate treatment effectiveness and lack of data supporting one treatment regimen over another. Therapeutic choices are based not only on histology but also on the clinical scenario, though no specific therapeutic choice is supported by robust trials in children. The KDIGO 2012 guidelines produced three recommendations for the treatment of IgA vasculitis with nephritis in children: Treatment of persistent proteinuria with ACE-I/ARB; treatment of persistent proteinuria with GFR >50 mL/min/1.73 m^2 with corticosteroids after ACE-I/ARB is unsuccessful; and treatment of crescentic IgA vasculitis with nephritis with nephrotic syndrome and/or declining kidney function as crescentic IgA nephropathy with corticosteroids and cyclophosphamide [136].

The first recommendation suggests that children with persistent proteinuria >0.5–1 g/d/1.73 m^2 are treated with ACE-I or ARB for at least 6-months (evidence grade 2D), even if proteinuria increases. This recommendation was highly debated, particularly in Europe, where there is a long tradition of treatment with IV steroid pulses and immunosuppression in children aiming at the complete resolution of crescents and glomerular endocapillary infiltration [139]. The rationale is that of a strong anti-inflammatory treatment blunting the spontaneous evolution of crescents to chronic sclerotic lesions. Further randomized controlled studies are required in these patients to compare short-term prednisone therapy with placebo, to enable advice for treatment [140].

The second recommendation calls for treatment of persistent proteinuria with GFR >50 mL/min/1.73 m^2 with corticosteroids after failure of treatment with ACE-I or ARB for 6 months. The advantage of pulse steroids over oral therapy has not been addressed by specific clinical trials in IgA vasculitis with nephritis, where the tendency to use pulse steroids is widespread in aggressive illness aiming at a rapid anti-inflammatory effect. The indication to use pulse steroids in children is usually considered at a lower percentage than the 50% crescents threshold suggested in KDIGO 2012. In the 2019 update of KDIGO on glomerular disease, IgA vasculitis with nephritis is not specifically considered; however, the need for discussion and update of ACE-I and steroid use in IgA nephropathy is stated [141, 142]. This item has been recently addressed by the European consensus produced by the SHARE initiative (single hub and access point for pediatric rheumatology in Europe) on diagnosis and treatment of IgA vasculitis [143]. The initiative produced 26 recommendations, 21 of which based on expert opinion due to lack of published evidence. SHARE criteria of severity of IgA vasculitis with nephritis are mostly based on absence or presence of crescents in less or more than 50% of glomeruli, according to the ISKDC classification. A lower proteinuria threshold to start prednisone is not established. SHARE puts the prompt start of steroids as a recommendation, although without a high grade of evidence (level 4, strength D). According to SHARE, mild cases of IgA vasculitis with nephritis with normal renal function and mild to moderate proteinuria deserve first line treatment with oral steroids. Pulses in association to immunosuppressive medications (azathioprine, mycophenolate mofetil, cyclosporine) are suggested as second line for more severe or resistant cases. Moderate IgA vasculitis with nephritis defined by GFR reduction or persistent proteinuria in the presence of $<50\%$ crescents requires a more aggressive treatment with oral or pulse corticosteroids as first line. The acute explosive onset of IgA vasculitis with nephritis in a high percentage of cases manifests clinically with rapidly deteriorating kidney function sustained by crescents in a high percentage of glomeruli. These cases can be assimilated to rapidly progressive IgA nephropathy or to vasculitis, and the treatments suggested by KDIGO recommendation follow the clinical practice for vasculitis [136].

The third recommendation advised treatment of crescentic IgA vasculitis with nephritis with nephrotic syndrome and/or declining kidney function treated as crescentic IgA nephropathy with steroids and cyclophosphamide, despite little evidence to support cyclophosphamide use in IgA vasculitis with nephritis. Cyclophosphamide was found to be useful to induce remission of proteinuria in a study in children, but the results were not conclusive when considering a protective effect on renal function or progression to renal failure [144]. In this RCT, no benefit of cyclophosphamide over placebo was reported but this trial suffered from the bias of late enrollment, several months after onset, as well as small sample size [144]. In a study of 54 adults with IgA vasculitis with nephritis, no additional benefit was demonstrated by adding cyclophosphamide to prednisone baseline therapy in 25 randomized patients versus 29 patients receiving steroids alone [145]. KDIGO 2012 guidelines for IgA vasculitis with nephritis included immunosuppressive drugs with a low evidence of efficacy (grade 2D) even in case of deteriorating renal function [136] and a systematic review was not conclusive on indications in 2015 [140].

Immunosuppressive Agents

Although not supported by controlled trials and guidelines, the use of immunosuppressive medications is widespread both in adults and in children with IgA vasculitis with nephritis. Many immunologically active drugs have been studied but most are small, uncontrolled series or case reports. Recently, the CureGN study, including 285 children (112 IgA vasculitis with nephritis and 173 IgA nephropathy) and 382 adults (49 IgA vasculitis with nephritis and 333 IgA nephropathy), reported use of immunosuppressive drugs at diagnosis in both children and adults: 16.3% of adults versus 8% of children [135]. The Cure GN study reports that in the last years, children were more frequently treated with mycophenolate mofetil (MMF) (20.5% in children vs. 10.2% in adults). Azathioprine was still used both in children and in adults (8.9% vs. 6.1%). In this cohort, adults had a more severe IgA vasculitis with nephritis, with renal failure and the need for aggressive treatment including steroids in the majority of the cases (85.7% in adults and 73.2% in children).

In clinical practice, however, particularly in rapidly progressive cases or with steroid resistant nephrotic syndrome, immunosuppression is generally used. The most frequent choice is between cyclosporine [146, 147], tacrolimus [148], and MMF. MMF is gaining favor in recent years due to limited side effects, satisfactory safety profile, and the clinical confidence derived from other types of nephritis, in both adults [149, 150] and children [151–154]. In a recent study, MMF was introduced in 18 children as early second-line therapy, within 3 months after the diagnosis of IgA vasculitis and 1 month after nephritis onset, after steroid pulses with incomplete response (33.8 ± 47.6 days after the diagnosis of IgA vasculitis with nephritis and 21.9 ± 17.5 days after initiation of pulsed methylprednisolone) [152]. The initial dose of MMF was 800–1200 mg/m^2/day, and remission of proteinuria was obtained within 3 months without significant side effects.

Cyclosporine A was compared to methylprednisone pulses in a study on 65 children with IgA vasculitis with nephritis, with similar results on long-term follow-up [146, 147, 155]. The use of rituximab (RTX) is also promising in children, extrapolated from experience in nephrotic syndrome and in other types of vasculitis. After initial case reports in adults [156–161] and children [162], small cohorts were published in recent years. RTX was effective in inducing remission of proteinuria in cases resistant to attempts with multiple drugs and in patients with steroid dependence without significant side effects [163]. Remission of proteinuria, stabilization of renal function, and absence of relapses were observed in 90% of patients who were treated with RTX. The dosage regimens were variable, from 2 doses of 750–1000 mg/m^2 administered 2 weeks apart to 4 weekly pulses of 375 mg/m^2. A review of findings in 22 adults, who were either steroid resistant or had contraindications to steroid therapy, reported some benefits on proteinuria reduction and prevention of GFR decline. To date, the published reports in children and adults are based on uncontrolled data with limited value as guidelines [164]. The alternative anti-CD20 monoclonal antibody, ofatumumab, was described as equivalently effective in one patient with IgA nephropathy [165]. There is anecdotal experience with the use of plasma exchange [166] and eculizumab [167, 168].

Long-Term Course

IgA vasculitis is typically self-limited with overall good prognosis and high probability of full renal function recovery within 6 months [100, 169]. However, relapse of disease is common among children (recurrence rate, 2.7%–66.2%) [170–172]. The long-term morbidity and mortality of IgA vasculitis are almost exclusively attributable to renal disease. Many observational studies have been conducted to elucidate the demographic and clinical characteristics associated with long-term outcome [23, 29, 94, 106, 122, 173, 174]. The difficulty in identifying clinical features or histologic findings associated with poor renal outcomes is the potential prolonged period of time between disease presentation and development of hypertension, chronic kidney disease, and end stage kidney disease.

Hypertension

Hypertension at presentation of disease has not been identified as a prognostic marker for poor renal outcomes. However, patients with a diagnosis of IgA vasculitis with nephritis are at a greater risk of developing hypertension compared with the general population. A case-control study evaluated the UK primary care database on 10,405 patients with childhood-onset and 2,828 patients with adult-onset IgA vasculitis, with age- and sex-matched controls. In this study, a 44% increase in emergent hypertension (cases 1.34% vs. controls 0.93%) in childhood onset IgA vasculitis was reported [173].

Complications During Pregnancy

A history of IgA vasculitis seems to increase the risk of complications during pregnancy. In a retrospective study of 44 women with history of IgA vasculitis, 36% of 44 pregnancies were complicated by hypertension and/or persistent proteinuria [86]. Another retrospective study from Australia reported 247 pregnancies in 121 women with a previous diagnosis of IgA vasculitis. They found that 10.9% (27/247 pregnancies) of women with a history of IgA vasculitis had gestational hypertension compared with 1.7% (10/556 pregnancies) in matched controls, with an odds ratio of 4.7 (95% CI 2.3, 9.8) [174].

Chronic Kidney Disease

Based upon published literature, 13–30% of patients with IgA vasculitis with nephritis develop CKD; the risk factors are summarized in Table 3 [26, 106, 114, 175, 176]. The UK primary care database study reported a 94% increased incidence of CKD in the population with a history of IgA vasculitis compared with controls (case 0.31% vs. controls 0.16%) [173]. CKD outcomes have largely been attributed to the presence and severity of nephritis in the acute phase. In a long-term study with mean follow-up of 23 years, 22% (17 of 78 children) had diminished renal function [86]. A more recent study found similar proportions, with 30% (47 of 159 patients) having poor renal outcomes at a mean follow-up of 37 months [107].

The presence of decreased eGFR and nephritic or nephrotic syndrome are risk factors for developing CKD [29, 106–108, 122, 177]. A meta-analysis found that nephrotic syndrome and mixed nephritic-nephrotic syndrome at presentation were associated with increased likelihood of poor renal outcome by 1.7 times and 4.5 times, respectively, compared with no renal involvement or minor urinary abnormalities, such as hematuria and/or non-nephrotic proteinuria. Poor renal outcome in this study was defined as hypertension, proteinuria >40 $mg/m^2/h$, increased serum creatinine, uremia, end stage

Table 3 Risk factors associated with prognosis of kidney health in IgA vasculitis

Kidney health indicator	Risk estimates (CI)	N	Reference
Risk factors for chronic kidney disease			
Proteinuria at onset	RR 1.09 (1.01, 1.18)	219	[178]
Persistent proteinuria	RR 1.44 (1.27, 1.64)	219	[178]
Impaired eGFR at onset	RR 1.97 (1.02, 3.78)	219	[178]
Interstitial fibrosis; tubular atrophy	$P = 0.009$	159	[107]
Risk factors for ESKD			
Persistent proteinuria	RR 1.78 (1.47, 2.14)	219	[178]
Risk factors for composite poor renal outcome			
Older age at onset	WMD 1.77 (0.35, 3.18)	969	[108][a]
Low eGFR as initial symptom	WMD -23.93 (−33.78, −14.09)	969	[108][a]
Higher degree of proteinuria	HR 1.20 (1.06, 1.35)	275	[29][b]
Nephrotic syndrome at onset	OR 1.74 (1.12, 2.70)	969	[108][a]
Nephritic-nephrotic syndrome at onset	OR 4.55 (2.89, 7.15) RR 11.9 (4.1, 41.5)	969 1133	[108][a] [179][c]
Crescents	OR 3.85 (2.37, 6.28)	969	[108][a]
S1 Glomerulosclerosis	HR 4.09 (1.11, 15.03)	275	[29][b]
M1 Mesangial hypercellularity	HR 4.02 (1.22, 13.30)	113	[105][d]
T1/2 Significant tubulointerstitial fibrosis	HR 12.28 (2.72, 55.27)	113	[105][d]

[a] Poor renal outcome defined as hypertension, proteinuria >40 mg/m^2/h, increased serum creatinine, uremia, ESKD, dialysis, or transplantation
[b] Poor renal outcome defined as 30% decrease in baseline eGFR, doubling of serum creatinine, or ESKD
[c] Poor renal outcome defined as nephrotic syndrome, nephritis, renal failure (serum creatinine above upper limit of normal), or hypertension
[d] Poor renal outcome defined as doubling of serum creatinine or ESRD
CKD chronic kidney disease; ESKD end kidney renal disease; IF/TA interstitial fibrosis/tubular atrophy; S1 any segmental glomerulosclerosis; M1 mesangial hypercellularity $\geq$50% of glomeruli; T1/2 significant tubule-interstitial fibrosis $>$25%, $>$50%, respectively; RR relative risk; WMD weighted mean difference; OR odds ratio; HR hazards ratio

kidney disease, dialysis, or transplantation [108]. A study of 219 biopsy-proven pediatric and adult cases of IgA vasculitis with nephritis identified persistent proteinuria at 1 year as a risk factor for doubling of serum creatinine (RR 1.44; 95% CI 1.27, 1.64) and end stage kidney disease (RR 1.78; 95% CI 1.47, 2.14). This study also identified that moderately impaired eGFR (eGFR 60–90 mL/min/1.73 m^2 in children or serum creatinine 1.5–3 mg/dL in adults) at presentation was associated with increased risk of doubling of serum creatinine at follow-up (RR 1.97; 95% CI 1.02, 3.78) [178]. Biopsy findings provide limited information regarding renal prognosis, as discussed above.

End Stage Kidney Disease

End stage kidney disease is an important long term outcome, but is infrequent. A retrospective study from Japan on 1120 children with IgA vasculitis found that 1.2% progressed to end stage kidney disease [35]. This finding was similar to a systematic review on 1133 children with IgA vasculitis that showed that 1.8% (95% CI 1.1, 2.8) of patients with IgA vasculitis are likely to progress to ESKD [179]. Kidney histology including crescents in over 50% glomeruli, interstitial fibrosis over 25%, mesangial hypercellularity and segmental glomerulosclerosis, nephrotic range proteinuria at presentation, and persistent proteinuria 1 year from onset of illness is associated with ESKD (Table 3).

Recurrence in Renal Allograft

In IgA vasculitis with nephritis, clinical recurrence in renal allografts is not uncommon; recurrence of mesangial IgA deposits is frequent [179–184]. Histologic recurrence is not necessarily associated with clinical recurrence. Some reports suggest that transplantation from living-related donors was associated with an increased risk of recurrence of the disease [184–186]. However, the association of living donation with recurrence of the disease and its effect on graft survival is not clear [186]. Data from the US national registry on organ transplantation showed histologically proven recurrence of IgA vasculitis in 13.6% of 339 transplant recipients with the disease. However, the 5- and 10-year allograft survival was not different between transplant recipients with IgA vasculitis compared with other conditions [185].

Although IgA vasculitis with nephritis in children is considered a self-limiting disease, a proportion of patients may show hypertension, chronic kidney disease, and ESKD, emphasizing the need for long-term follow-up [96, 178, 185].

Abstract

The nomenclature of vasculitides has been revised in light of recent understanding of the pathogenesis of these diseases. The Ankara 2008 childhood classification criteria aid in the management of pediatric patients with vasculitis. The most common childhood vasculitis, IgA vasculitis (Henoch-Schönlein purpura) is reviewed elsewhere. The other common vasculitis of childhood, Kawasaki disease affects medium-sized arteries but rarely the kidney.

ANCA-associated vasculitis (AAV) often affects the kidney, mainly in form of pauci-immune necrotizing glomerulonephritis. The most common AAV is granulomatosis with polyangiitis (Wegener's granulomatosis). Polyarteritis nodosa (PAN) is a medium-sized arteritis that may involve the arteries of the kidneys as well. Deficiency of adenosine deaminase (ADA2) might mimic PAN and should be considered in patients with features of PAN with family history, or those with stroke or with hematological and/or immunological abnormalities. Takayasu arteritis and rarely Behçet disease can also affect the vessels of the kidney. Recent management and treatment strategies guide us in the care of these children.

Keywords

ANCA-associated vasculitis · child · IgA Vasculitis · Kawasaki disease · Polyarteritis nodosa · Deficiency of adenosine deaminase · Takayasu arteritis

Synonyms

GPA: Wegener Granulomatosis; EGPA: Churg Strauss Syndrome

Introduction

The vasculitides are a group of rare diseases that involve inflammation in walls of blood vessels. This inflammation leads to narrowing or aneurysm of the vessel resulting in protean systemic manifestations. The kidney is a frequently affected target organ.

Vasculitides have predilections for the size of the vessel and the organ they affect. A number of attempts have been made to classify vasculitis syndromes based on these features. Recently the nomenclature criteria suggested by the Chapel Hill Consensus Conference (CHCC) has been revised [1]. The small vessel involvement is now divided into two main groups based on the pathogenesis of these diseases (Table 1). Specific vasculitis eponyms have been replaced by suitable descriptive terms with pathophysiologic specificity where feasible [1]. Some eponyms are retained; another novelty is the addition of new categories:

- Variable vessel vasculitis includes vasculitides that may affect any vessel size, such as Behçet disease
- Single vessel vasculitis includes isolated vasculitides, such as central nervous system vasculitis
- Vasculitis associated with systemic disease such as systemic lupus erythematosus
- Vasculitis with probable etiology, for example, hepatitis associated, monogenic diseases with vasculitis.

The aforementioned CHCC are mainly definition criteria. Almost three decades earlier, the American College of Rheumatology had suggested classification criteria for adults for each vasculitis [2–4]. Therefore, in 2006 a group of pediatric rheumatologists and nephrologists published the classification criteria for the common childhood vasculitides with names at that time of Henoch-Schönlein purpura, Kawasaki disease, polyarteritis nodosa, Wegener granulomatosis, and Takayasu arteritis [5]. These criteria have been revised and validated and published as the Ankara 2008 criteria, endorsed by EULAR (European League Against Rheumatism), PRINTO (Pediatric Rheumatology International Trials Organization), and PRES (Pediatric Rheumatology European Society) [6]. One should remember that all the mentioned criteria are classification criteria and the

Table 1 New classification of childhood vasculitides. (Modified from Ref. [1])

Large-vessel vasculitis
Takayasu arteritis (TAK)
Giant cell arteritis (GCA)
Medium-vessel vasculitis
Polyarteritis nodosa (PAN)
Kawasaki disease (KD)
Small-vessel vasculitis
Anti-neutrophil cytoplasmic antibody (ANCA) associated vasculitis (AAV): Microscopic polyangiitis (MPA); granulomatosis with polyangiitis (Wegener, GPA); Eosinophilic granulomatosis with polyangiitis (Churg-Strauss syndrome, EGPA)
Immune complex vasculitis: Anti-glomerular basement membrane (anti-GBM) disease; cryoglobulinemic vasculitis; IgA vasculitis (Henoch-Schönlein); hypocomplementemic urticarial vasculitis (anti-C1q vasculitis)
Variable vessel vasculitis
Behçet disease
Cogan syndrome
Single-organ vasculitis
Cutaneous leukocytoclastic angiitis
Cutaneous arteritis
Primary central nervous system vasculitis
Isolated aortitis
Vasculitis associated with systemic disease
Lupus vasculitis
Rheumatoid vasculitis

diagnosis of these diseases depend on the judicious assessment of the patient.

The most common vasculitides of children are IgA vasculitis (Henoch-Schönlein purpura) and Kawasaki disease (KD). The former is reviewed in a separate chapter. The remaining primary vasculitides that affect the kidney will be reviewed.

ANCA Associated Vasculitides

Anti-neutrophil cytoplasmic antibody (ANCA) associated vasculitides (AAV) are a group of disorders that can cause a rapidly progressive glomerulonephritis with chronic, often relapsing disease, which can be organ or life threatening with high morbidity and mortality despite immunosuppression. There are three main conditions characterized by necrotizing inflammation of small to medium vessels in association with autoantibodies against the cytoplasmic region of the neutrophil (ANCA), including the commonest condition, granulomatosis with polyangiitis (GPA; formerly Wegener granulomatosis), microscopic polyangiitis (MPA), and eosinophilic granulomatosis with polyangiitis (EGPA; formerly Churg-Strauss syndrome). Children with all three conditions present with rapidly progressive glomerulonephritis associated with necrotizing glomerulonephritis (capillaritis) and is characteristically pauci-immune (few or no immune deposits, affecting small vessels, i.e., capillaries, venules, or arterioles) [1]. Renal limited vasculitis is a term used for renal histopathology (previously classified as pauci-immune, necrotizing crescentic, or ANCA-associated glomerulonephritis) in the absence of vasculitis in other organs.

Approximately 80% patients with renal limited vasculitis are positive for ANCA, predominantly myeloperoxidase (MPO-ANCA), and thus may be cohorted with patients diagnosed as MPA. These disorders are associated with either proteinase-3 (PR3) or MPO-ANCA. However, MPO is more often associated with microscopic polyangiitis, whereas PR3-ANCA is more common in granulomatosis with polyangiitis.

Microscopic Polyangiitis

Necrotizing glomerulonephritis is frequently seen with necrotizing arteritis involving small and medium-sized arteries and pulmonary capillaritis [1]. The presence of ANCA directed often against the MPO antigen, shown by ELISA and/or strong perinuclear staining pattern by indirect immunofluorescence, has been added to the definition in children [5, 6].

Pathogenesis: Both in vitro and in vivo experimental data support the pathogenic role of ANCA in MPA [7]. In fact, a mice model has introduced direct role of the injury by anti-MPO: Anti-MPO IgG led to focal necrotizing and crescentic GN with paucity of glomerular immune deposition, which mimics the human disease [8]. However, we still need further data on the factors that are effective in production of ANCA in the first place, and the genetic factors involved.

A recent genome wide association study has provided important information [9]. This study showed that the pathogenesis of AAV has a genetic component and shows genetic distinctions between GPA and MPA that are associated with ANCA specificity. Anti-MPO-ANCA, which is more common in MPA, was associated with certain SNPs in HLA-DQ [10].

Clinical and laboratory features: The presence of histopathologically proven necrotizing glomerulonephritis along with a positive ANCA (often MPO-ANCA) titer in the absence of granulomatous lesions and upper respiratory tract involvement leads to a diagnosis of MPA [6]. Childhood cases have been reported as small series [11–15]. Hattori et al. [13] have reviewed 34 ANCA-seropositive Japanese pediatric patients with biopsy-proven pauci-immune necrotizing crescentic glomerulonephritis and 21 were classified as MPA with disease similar to that of adults except for female predominance. Patients who subsequently developed end-stage kidney disease (ESKD; $n = 9$) had significantly worse renal function and more chronic pathological lesions at diagnosis compared with patients with favorable renal outcome [13]. Forty-eight pediatric MPA patients were also subsequently described with similar features [11].

In a series reported by Peco-Antic et al., 57% patients had pulmonary-renal syndrome, one developing chronic kidney disease and two with acute kidney injury progressed to ESKD [15]. In another series of six pediatric patients from India, three had the pulmonary renal syndrome [12]. We reported a series of 25 patients with PAN, 10 of whom were classified as small vessel necrotizing arteritis (MPA) [16]. Six developed renal dysfunction, three of them had pulmonary-renal syndrome and all had high MPO-ANCA levels. Six had percutaneous renal biopsies showing pauci-immune, necrotizing crescentic glomerulonephritis, and four (40%) progressed to chronic kidney disease [16].

Laboratory investigations: An immunofluorescence testing for ANCA often reveals a p-ANCA pattern. Further ELISA testing should also be ordered which typically will show a high titer of MPO-ANCA [6, 17]. Urinalysis will reflect the glomerular disease with proteinuria, hematuria, and an active urine sediment with casts. Renal function tests were impaired in 30–60% of patients reported in a pediatric series [18, 19]. A chest x-ray is required in all patients and in patients with abnormalities, then chest CT is warranted to define the extent of lung involvement.

Pathology: Percutaneous renal biopsy is indicated in children with renal involvement. MPA is characterized by necrotizing vasculitis with few or no immune deposits, affecting capillaries, venules, or arterioles [7]. All arterial lesions are usually at the same stage. Kidneys show necrotizing glomerulonephritis, which is focal and segmental to severe diffuse and crescentic (Fig. 1). No immune deposits are detected on immunofluorescence or electron microscopy. Sausage

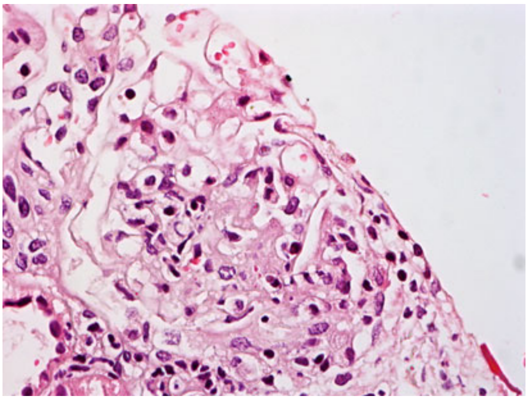

Fig. 1 Microscopic polyangiitis with segmental necrosis and proliferation of parietal cells of the Bowman's capsule in the periphery of the glomerulus

shaped microaneurysms of interlobular arteries are also reported [15, 20–22].

Differential diagnosis includes pauci-immune glomerulonephritis including EGPA, severe cases of IgA vasculitis, and coagulation disorders. Etiologies of necrotizing and crescentic glomerulonephritis, pauci-immune glomerulonephritis, are generally best differentiated clinically, and not histologically [20, 23].

Treatment and Prognosis: The prognosis of AAV in children with MPA, GPA, and EGPA has substantially improved with results of controlled studies in adults and new treatment modalities. EUVAS (European Vasculitis Study group) has carried out multicenter, controlled studies that have provided us evidence for treatment of these patients. Treatment for AAV can be divided into two parts, induction and maintenance.

For induction treatment, patients should receive corticosteroids and cyclophosphamide. In patients with severe disease, three daily pulse of intravenous methylprednisolone is suggested to be continued with oral corticosteroids. Daily oral prednisolone (1–2 mg/kg/d) and intravenous cyclophosphamide pulses (500–750 mg/m^2, reduced to 250 mg/m^2 if renal dysfunction; every 2–4 weeks) is initiated as induction therapy. Whether cyclophosphamide is to be given via an oral or intravenous route is a matter of debate. The CYCLOPS trial in adults showed that pulse cyclophosphamide may be associated with a higher relapse risk than oral therapy [24]. However, there was no difference in renal function at a median follow-up of 4.3 years ($P = 0.82$). Other agents employed in remission induction include anti-TNF therapy and MMF. Increasing consideration is being given to the use of rituximab for severe or relapsing disease, particularly for those with concerns regarding glucocorticoid or cyclophosphamide toxicity.

For maintenance treatment, the prednisolone dose is tapered following clinical and laboratory response, but not before 4 weeks. A suggested wean is to reduce prednisolone dose by 10 mg every 2 weeks, to reach a minimum of 5–10 mg/d and subsequently on alternate days, which may be continued for a year after clinical remission. For maintenance regimen, the total cyclophosphamide dose has been a concern for pediatricians. The CYCAZAREM trial showed that the replacement of cyclophosphamide with azathioprine at 3 months is effective for disease control [25]. Methotrexate has been shown to be an alternative for maintenance treatment especially for non-renal manifestations [26]. Another randomized trial that compared mycophenolate mofetil (MMF) to azathioprine for remission maintenance in AAV showed that the latter was less effective than the former in maintaining remission [27].

Plasmapheresis, in addition to immunosuppressive treatment, may be used for life-threatening disease. The previous MEPEX study has shown that plasmapheresis is advantageous over pulse corticosteroids in patients with renal dysfunction [28]. However, the new PEXIVAS study has not confirmed these results.

Two controlled studies in 2010, one from Europe and the other from North America, confirmed the efficacy of anti-B cell therapy in patients with AAV [29, 30]. These two studies compared rituximab and cyclophosphamide for the induction of remission with different protocols. There were no significant differences in remission rates nor adverse events. Intravenous rituximab is now a safe alternative for adult patients who are resistant or intolerant to cyclophosphamide [29, 30]. A pediatric study is underway. For the time being rituximab should be considered especially in children with relapsing disease who have already received cyclophosphamide.

Granulomatous Polyangiitis (GPA) (Wegener Granulomatosis)

GPA is defined as a necrotizing granulomatous inflammation of the upper and lower respiratory tract, necrotizing vasculitis affecting small to medium-sized vessels and glomerulonephritis [1]. GPA is a vasculitides with major renal involvement like MPA. Children frequently have constitutional symptoms, such as fever, anorexia, and weight loss with multiorgan or generalized disease. According to the Ankara 2008 criteria revised for childhood, three of the following six should be present to classify as GPA [6]:

- Renal involvement
- Upper airway involvement (70 to 100%) with recurrent epistaxis or sinusitis
- Laryngo-tracheo-bronchial stenosis
- Pulmonary involvement (chest x-ray or CT showing diffuse pulmonary infiltrates, pulmonary nodules, cavitating lesions, and granulomata without cavitation)
- Histopathology (granulomatous inflammation)
- Positive ANCA

Pathogenesis: The etiology of GPA is not known; the endothelium itself is the target for initial injury. Studies suggest a direct involvement of ANCA in the pathogenesis of the disease; inflammatory cells primed with ANCA are cytotoxic to endothelial cells [31, 32]. It is known that in vitro ANCA induces endothelial injury through activation of neutrophils and the reactive oxygen molecules, proteases, and cytokines that they release. ANCA is “active” against the proteinase 3 (PR3) on neutrophils in GPA. In vitro ANCA can further activate neutrophils to release reactive oxygen species, which in conjunction with neutrophils may damage and result in inflammation of endothelial cells [7]. There is a convincing mouse model defined with MPO-ANCA, mimicking the human disease; however, the same results were not obtained with PR3-ANCA [7].

There have been a number of genetic associations with the disease including HLA antigens, a region on chromosome 6p21.3 [9]. Recently a genome wide association study (GWAS) in PR3 and MPO-ANCA associated AAV patients has provided us further important information: In GPA, anti-proteinase 3 ANCA was associated with HLA-DPB1 and the genes encoding α(1)-antitrypsin (SERPINA1) and proteinase 3. Polymorphisms of the natural inhibitor of PR3, alpha-1-antitrypsin, had been previously implicated for increased risk and morbidity of GPA. This study suggested that the response against PR3 is a pathogenic feature of GPA [9].

Clinical and laboratory features: Data from small pediatric series reflect that 90% of children with GPA present with symptoms related to the upper and lower respiratory tract vasculitis, sinusitis, epistaxis, and nasal inflammation [33–38]. Lower-airway inflammation manifests as cough, dyspnea and hemoptysis; 30% have chest x-ray abnormalities [33–35, 38]. Among 25 patients reported by Akikusa et al., renal involvement was present in 22, and upper airway involvement in 21 patients at presentation and 24 during follow-up [33]. Twenty patients had initial pulmonary involvement, most commonly nodules (44%) and pulmonary hemorrhage (44%), and four (16%) had venous thrombotic events [33].

Renal involvement occurs in 10 to 100% of affected children and contributes to significant morbidity [33–35, 38]. Patients present with urinary sediment abnormalities or mild renal dysfunction and glomerulonephritis diagnosed by biopsy is common. In the aforementioned series of 25 children, glomerulonephritis was present in 22 patients at presentation of disease [33]; only one of 11 patients who presented with or developed renal dysfunction had normalization of serum creatinine [33]. Necrotizing glomerulonephritis is one of the most serious manifestations in GPA associated with renal dysfunction [33].

Clinical findings include blurred vision, eye pain, conjunctivitis, episcleritis, and otitis media [33–35, 38]. Neurological involvement presents as cranial nerve palsies, seizures, or neuropathies [32]. Skin lesions include palpable purpura, nodules, ulceration, and gangrene. Musculoskeletal symptoms may be present but cardiac involvement is rare.

A cytoplasmic pattern on immunofluorescent staining of ANCA (c-ANCA) is present in 70–90% of patients with active GPA [1, 33, 35]. ELISA tests detecting PR3-ANCA confirm this specificity in a high proportion of patients. Investigations show elevated white blood count and acute phase reactants. Urinalysis shows hematuria, proteinuria, and casts when there is renal involvement. Chest x-ray and pulmonary function tests are indicated for assessment of lung disease [6, 32]. The chest x-ray may show nodular infiltrates and nodules that might require assessment with chest CT.

Pathology: The typical histologic lesion of granulomatous polyangiitis is necrotizing vasculitis of small arteries and veins, usually with granuloma formation (Fig. 2). Granulomas may be intravascular or extravascular. Multiple organ systems can be involved. Biopsy of paranasal sinus, nasopharyngeal, or tracheal lesions reveal acute or chronic inflammation or frank vasculitis with or without granulomas. Pulmonary lesions microscopically show granulomas and vasculitis. Renal involvement is observed as necrotizing glomerulonephritis, often with necrosis, cellular crescents, and usually with glomerular thrombosis. Interstitial inflammation is common, and renal papillary necrosis is seen in ~20%. Unlike the biopsy of lung or sinuses, the renal biopsy rarely shows a granuloma [1, 7, 23, 31, 32].

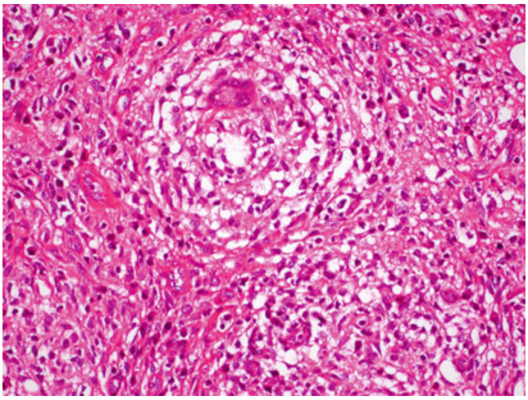

Fig. 2 GPA/WG. Necrotizing granulomatous inflammation of the vessel with multinucleate giant cells

Differential diagnosis is similar to MPA, but in addition, other granulomatous diseases such as sarcoidosis, lymphomatoid granulomatosis, and tuberculosis are also included.

Treatment and Outcome: Treatment of GPA and MPA is similar. In fact, most of the adult studies published by EUVAS include MPA and GPA patients together [26–28, 39, 40]. Rituximab has been shown to be effective and is an increasingly used form of induction and maintenance therapy [30, 41]. Relapses are frequent as in the adults. Treatment with cotrimoxazole may help reduce the frequency of relapses. The overall data support the prognostic impact of renal function at diagnosis and of renal relapses during follow-up.

Eosinophilic Granulomatosis with Polyangiitis (EGPA) (Churg-Strauss Syndrome)

EGPA is very rare in childhood and accounts for ~2% children with primary systemic vasculitis. EGPA is a necrotizing vasculitis of small and medium-sized vessels that predominantly affects the upper airway and lung. EGPA is defined as a systemic necrotizing vasculitis with hypereosinophilia and extravascular granulomas along with asthma [1, 42]. Patients present with history of asthma and allergy, involvement of paranasal sinuses and peripheral nervous system, and eosinophilia. Skin involvement and vasculitis is similar to PAN. However, this pauci-immune small vessel vasculitis is distinguished from GPA and MPA by the presence of granulomatous inflammation and asthma with hypereosinophilia. Among adult patients, ~20% show glomerulonephritis and renal dysfunction [43].

The laboratory work-up is similar to MPA or GPA but the presence of ANCA is less common in children (0 to 25%). Typically, p-ANCA pattern is expected but specific laboratory tests are required for the diagnosis and differential diagnosis.

Pathology: The classic findings of EGPA are eosinophil-rich, granulomatous inflammation involving the respiratory tract, and necrotizing vasculitis affecting small to medium-sized vessels

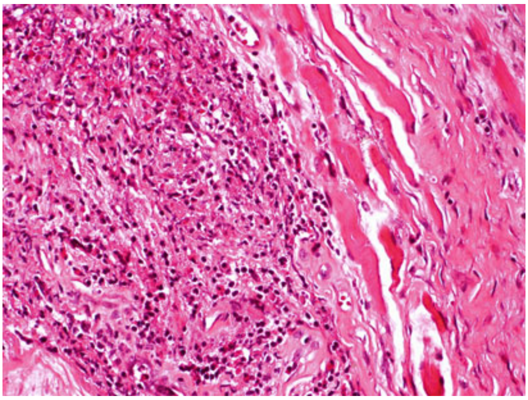

Fig. 3 EGA/CSS. Granulomatous vasculitis with multinucleate giant cell and eosinophils

(Fig. 3). Renal manifestations include pauci-immune crescentic glomerulonephritis, renal arteritis, arteriolitis, and medullary angiitis. Microscopic features on renal biopsy include necrotizing and crescentic glomerulonephritis without immune complex deposition, fibrinoid necrosis of arteries, and interstitial nephritis with eosinophilia [7, 44].

Treatment of EGPA is similar to that of other AAV.

Kawasaki Disease

Definition and classification: Kawasaki disease is a vasculitis affecting the skin and mucosa, characterized by preference for the coronary vessels. According to the Chapel Hill criteria, Kawasaki disease is defined as arteritis involving large, medium-sized, and small arteries and associated with mucocutaneous lymph node syndrome [1]. The disease is classified based on presence of fever of at least 5 days duration, plus four of the following five features [5, 45, 46].

- Changes in peripheral extremities (edema and/or erythema of the hands and feet and subsequent periungual desquamation), or desquamation of the perineal area (Fig. 4)
- Polymorphous exanthema mainly truncal
- Bilateral non-purulent conjunctival injection
- Changes of lips and oral cavity: injection of oral and pharyngeal mucosa
- Cervical lymphadenopathy, usually unilateral

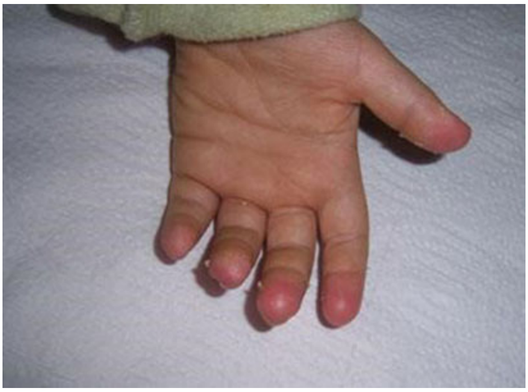

Fig. 4 Peeling in the hands of a patient with Kawasaki disease

Pathogenesis: As is the case of many vasculitides, Kawasaki disease is an abnormal immune response to environmental or infectious trigger(s), in genetically predisposed individuals. Superantigens have been frequently implicated as the causative agents. This is supported by the skewing of the T-cell receptor Vβ repertoire [46]. The fact that Kawasaki disease mainly affects young children may be due to the timing of the exposure of the environmental agent in a naïve immune pathway.

Clinical features: The clinical features of the disease are as above [45, 46]. Although renal involvement is rare, nephrologists should be aware of the disease spectrum and rare involvement of renal vessels. Pyuria and urethritis are frequent [46, 47]. Vasculitis might rarely affect the renal arteries, manifested as renal artery aneurysms [48]. Angiographic evaluation of other mid-size arteries should be done if there are suggestive features, such as hypertension. Renal parenchymal involvement and acute kidney injury have been reported only in rare case reports, including acute interstitial nephritis [49].

As for laboratory investigations, a full blood count is mandatory. Thrombocytosis is common at the second week of the disease; however, platelet counts may be low in the early phase of the disease [46]. Acute phase reactants are high. Every child suspected of having KD should have an echocardiography to investigate for coronary artery involvement.

Pathology: Systemic vasculitis is the characteristic pathological finding in Kawasaki disease [50, 51]. In addition to vasculitis and inflammatory lesions in various organs and the heart, interstitial nephritis and cystitis have been reported [50–52]. Histologically, coronary arteritis begins 6–8 days after onset of the disease. The inflammation is composed of neutrophils, monocytes, and macrophages in all layers of the artery [50–53]. Arterial dilatation begins, and progressive destruction of the adventitia causes saccular aneurysms. These aneurysms can thrombose or rupture [50–53]. Varying incidence of panarteritis in kidneys of Kawasaki disease is reported [52, 53]. Asaji et al. reported that 73% patients had features of angiitis or scars in their kidney. Arteritis and granulomatous inflammation were noted in patients who died within 1 month after the onset of KD. Arteritis in the kidney was milder than coronary arteritis, and developed several days later than the coronary arteritis. Panangiitis was localized to the interlobar arteries and rarely seen in arcuate and intralobular arteries [52]. Glomerular changes, such as segmental or global glomerulosclerosis and focal segmental proliferation, and intracapillary proliferative glomerulonephritis are reported [52, 53].

Treatment and Prognosis: Recently experts have participated in the European Single Hub and Access point for pediatric rheumatology in Europe initiative (SHARE) for recommendations for therapy for Kawasaki disease [54]. Treatment includes intravenous immunoglobulin (IVIG) administered at 2 g/kg along with salicylates at a dose of 30–80 mg/kg/day [46, 48, 54]. Aspirin should be given for 6 weeks or until the ESR and platelet counts normalize and lifelong for those who have any cardiac involvement [46, 48, 54]. SHARE recommendations also suggest to give corticosteroids to patients with severe illness, including those who are IVIG resistant, those with features of shock and those with coronary aneurysms [54]. Biologics should be considered in severe and steroid resistant cases as well.

Kawasaki disease is the top cause of acquired heart disease in the western world [46]. Therefore, early recognition of the disease and administration of IVIG in the first 10 days of initiation is crucial. The follow-up of patients with coronary involvement should always include a pediatric cardiologist. The prognosis is excellent in patients treated within the first days of their disease, since Kawasaki disease is self-limiting if the coronaries are spared.

Childhood Polyarteritis Nodosa (PAN)

Definition and Classification: The Chapel Hill Nomenclature criteria 2012 defines polyarteritis as necrotizing arteritis of medium or small arteries *without* glomerulonephritis or vasculitis in arterioles, capillaries, or venules, and not associated with circulating ANCA [1].

Childhood PAN differs from microscopic polyangiitis (MPA) through the absence of necrotizing glomerulonephritis and absence of ANCA. Renal involvement in childhood PAN occurs through necrotizing arteritis of the renal vascular bed, whereas the presence of necrotizing glomerulonephritis classifies the child as MPA [1]. The renal features are related to the involvement of the medium sized vessels in the kidney. In a large adult series, Agard et al. reported that the initial manifestations of both classic PAN and MPA were similar, except for gastrointestinal involvement and peripheral neuropathy being more frequent in PAN [18].

The Ankara 2008 pediatric criteria for the classification of polyarteritis nodosa (PAN) have been validated (Table 2) [6]. The new criteria of childhood PAN include the demonstration of necrotizing arteritis in small and medium size arteries or aneurysms in medium-sized arteries by imaging techniques, which reflects the necrotizing inflammation in these vessels [6].

Pathogenesis: As in Kawasaki disease, infections are implicated as a triggering agent in a predisposed host. In fact, a number of reports point to the role of streptococci in childhood PAN, especially in cutaneous PAN [55]. On the other hand, other forms of PAN have more specific pathogenesis: hepatitis B related PAN is an immune complex disease and is now classified as "vasculitis associated with probable etiology" [1]. This association has declined with recent

Table 2 EULAR/PRINTO/PRES (Ankara 2008) classification criteria for childhood PAN [6]

Evidence of necrotizing vasculitis in medium or small arteries or an angiographic abnormality showing aneurysm, stenosis, or occlusion of a medium- or small-sized artery (histopathology or angiography mandatory), plus one out of five of the following criteria:
1. Skin involvement (livedo reticularis, tender subcutaneous nodules, other vasculitic lesions)
2. Myalgia or muscle tenderness
3. Systemic hypertension (systolic or diastolic blood pressure greater than 95th percentile for age, sex, and height centile)
4. Peripheral neuropathy (sensory peripheral neuropathy, or motor mononeuritis multiplex)
5. Renal involvement: Proteinuria (>0.3 g/24-h proteinuria or urine albumin: creatinine ratio >30 mg/mmol on spot morning sample; ≥2+ protein on dipstick); hematuria or red cell casts (>5 red cells/high power field; red blood cells casts in urinary sediment); or impaired renal function (measured or calculated glomerular filtration rate <50 ml/min/1.73 m^2)

vaccination protocols. Recently, an association of childhood PAN with pathogenic variants in *MEFV* (familial Mediterranean fever) has been shown in Turkish children [56, 57].

Clinical features: PAN presents with general findings and wide range of symptoms. The disease often has an insidious onset with constitutional symptoms [6, 58]. Children with PAN present with constitutional symptoms, skin manifestations, myalgia, and organ involvement. In an effort to define the characteristics of childhood PAN throughout the world, we recruited 110 patients from 21 pediatric centers from over the world [58]. The mean patient age was 9.1 ± 3.6 years (range 1–16 years), with equal number of girls and boys. Features were similar to those reported in small series and were different from adult data. The mean patient age was 9.3 and 7.5 years in two other series, both including infants [59, 60]. In the aforementioned multinational study, fever (87%), myalgia (83%), and skin (88%) manifestations were the leading features, whereas renal involvement was reported in 19% [58]. Pulmonary and cardiac disease was reported in 11% and 14%, respectively, with peripheral neuropathy and CNS involvement seen in few patients. Similar frequencies of clinical features were reported in smaller studies from India and Croatia [59, 60]. A number of patients do not have typical presentations of classic PAN, but have inflammation in arteries of varying size in organ systems. Erden et al. have compared the features of PAN in children and adults from a tertiary center [61]. Joint and skin involvement were more common in children (86.7% vs. 59.1%; 93.3% vs. 72.7%, respectively), while renal and neurologic involvement were more frequent in adult patients (50% vs. 20%; 59.1% vs. 40%, respectively; all $P > 0.05$) [61].

Renal involvement presents with systemic vasculitis along with an ischemic kidney due to the inflammation of the medium-sized arteries [6, 62]. The glomerular capillaries are not affected. Renal involvement in childhood PAN may present as hypertension reflecting the necrotizing vasculitis of the renal arteries. In fact, in the series of 110 children with PAN, 43% of patients with the systemic disease had hypertension. The diagnosis was confirmed by angiography in 52.5% patients [58].

Full blood count may reveal anemia, leukocytosis, and thrombocytosis. The work-up should include urinalysis, monitoring renal function, acute phase reactants for disease activity, and necessary imaging [63]. Imaging of mid-sized arteries is required to search for aneurysm in a patient who presents with hypertension or ischemic abdominal pain. In a review of the angiograms in PAN patients, Brogan et al. concluded that the most reliable non-aneurysmal findings were perfusion defects, presence of collateral arteries, lack of crossing of peripheral renal arteries, and delayed emptying of small arteries [62]. Children with medium or large vessel aneurysms or those with renal perfusion defects may have impaired kidney function. In patients without hypertension, renal involvement is unlikely and mesenteric or hepatic arteritis may be the cause of abdominal pain and ischemia. CT angiography may be sufficient for the diagnosis of PAN, although not as sensitive as a classic angiogram.

Targeted tissue biopsy is indicated, although percutaneous renal biopsy is usually not indicated since the glomerular capillaries are spared. The diagnosis of PAN can be confirmed by histopathological demonstration of necrotizing vasculitis and/or radiologic demonstration of aneurysms and other angiographic typical findings.

The differential diagnosis depends on the spectrum of organ involvement. Other forms of vasculitis and secondary vasculitides need to be considered. Infections such as bacterial endocarditis with microembolism as well as autoinflammatory syndromes may mimic features of PAN. Pathogenic variants in *ADA2,* encoding adenosine deaminase 2 results in a syndrome of intermittent fevers, early-onset lacunar strokes and neurovascular manifestations, livedoid rash, hepatosplenomegaly, and systemic polyarteritis nodosa like vasculopathy, have been described [64].

Pathology: PAN is characterized by necrotizing inflammation throughout the wall of small to medium-sized arteries [1, 12, 17, 19, 65]. The kidney, gastrointestinal tract, liver, skin, pancreas, muscles, and other sites can be involved. Acute lesions are characterized by fibrinoid necrosis of the arterial wall with inflammation (Fig. 5). Fibrinoid necrosis may be circumferential, but is often localized to a single artery segment. Inflammation is composed of neutrophils early in the disease, and later, lymphocytes, plasma cells, and macrophages (Fig. 6). Healing lesions show marked fibrous thickening of the arterial wall with fragmentation of the elastic lamina. Individual vessels reveal different stages of the inflammatory process [17, 19, 65].

Intravascular thrombosis is a frequent sequel to the vasculitis leading to ischemia and infarction in the areas supplied by these vessels. Necrosis of muscle in vessel wall may lead to focal aneurysm as a late complication. Necrotizing vasculitis of renal, interlobar, and arcuate arteries at branch points with aneurysmal dilatation, fibrinoid necrosis, and neutrophilic infiltration of vessel wall are observed in the kidney. Later, perivascular tissue and media shows mononuclear infiltration and fibrosis, and recanalization of the thrombosed vessel is seen. Glomerular lesions (ischemic collapse and sclerosis) are not specific to PAN [1, 12, 65].

Treatment and Prognosis: Treatment of systemic PAN is based on uncontrolled pediatric data and recommendations on patients with adult-onset disease. There is need for prospective multicenter studies to define the efficacy and duration of immunosuppressive treatment. A group of experts recently proposed recommendations for treatment of systemic vasculitis, including PAN [63]. According to these recommendations, management of systemic vasculitis requires induction treatment, followed by less intense maintenance therapy. The former may include corticosteroids and intravenous cyclophosphamide [63]. For maintenance treatment, azathioprine, mycophenolate mofetil, and methotrexate are first-line agents;

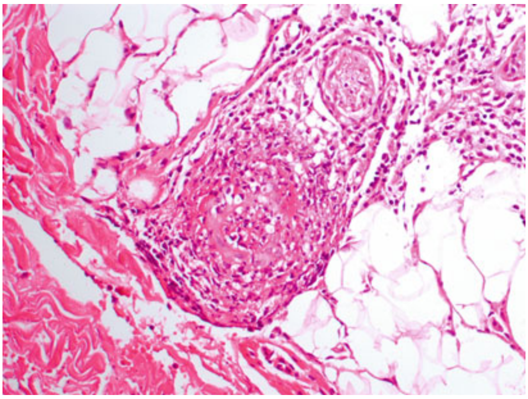

Fig. 5 PAN. Fibrinoid necrosis and inflammation in a medium-sized artery wall

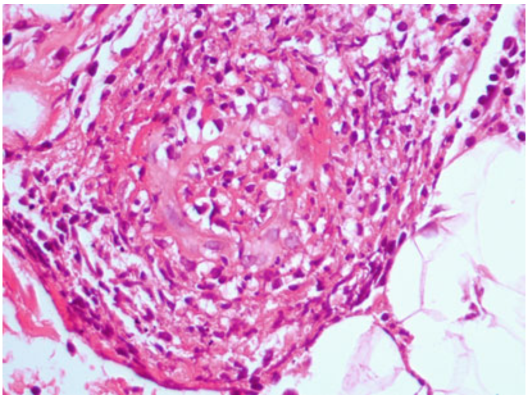

Fig. 6 PAN. Fibrinoid necrosis with neutrophilic infiltration in vessel wall

biologics may be considered for recalcitrant disease [63]. Maintenance treatment is advised for 12–36 months, depending on course of the disease. The prognosis of PAN has improved in recent years due to timely diagnosis and effective therapy.

Deficiency of Adenosine Deaminase 2 (ADA2)

Definition: Deficiency of ADA 2 is a monogenic form of vasculitis [64, 66]. The disease is due to mutations in the gene *ADA2* or *CECR1* encoding ADA2 [64–67], leading to disease mimicking PAN, with inflammation of medium-sized arteries in the kidney and elsewhere.

Pathogenesis: ADA2 is highly expressed in myeloid cells and produced by activated monocytes, macrophages, and dendritic cells [65–67]. The inflammatory component of the disease is thought to be due to monocyte-macrophage polarization toward the M1 (inflammatory) subset [65, 67]. M1 macrophages are known to promote inflammation and tissue damage. ADA2 appears to be critical for the maintenance of vascular integrity and ADA2 deficiency is thought to disrupt endothelial cells, which may explain the vasculitic and neurologic component of the disease. Livedoid rash and other types of nonspecific skin rash such as nodular rash and macular erythema are also described [65–67].

Clinical features: Clinical presentation and age of onset vary widely. Medium-sized arteries of any organ system can be affected [64, 65]. Necrotizing inflammation of renal arteries results in microaneurysms or stenosis on CT angiography. Other features include livedoid rash and early cerebrovascular accidents [64–67]. DADA2 patients also display features of clinical inflammation such as low-grade fever or high CRP. Cutaneous manifestations are the most common feature of deficiency of ADA2, present in three-fourths of patients [64–67].

Of all patients, 50% have one or more neurological events. MRI shows acute or chronic lacunar ischemic infarcts located in the deep-brain nuclei and/or the brain stem, with sparing of subcortical white matter. Onset of ischemic strokes can be in infancy; hemorrhagic stroke and intracranial bleeding may also occur [67]. Hematological involvement may be present in the form of varying degrees of cytopenias [68]. We have previously reported that patients with deficiency of ADA2 may not have the thrombocytosis of classic PAN, and instead show thrombocytopenia [65]. Hypogammaglobulinemia is not rare, and other mild immunological abnormalities and fluctuating titers of autoantibodies may be detected [64, 67].

Red flags for the diagnosis of ADA2 deficiency include a family history of similar disease, and/or early cerebrovascular accidents, absence of thrombocytosis and immune abnormalities in a patient with a PAN-like presentation [65]. Diagnosis depends on measuring serum ADA2 activity and carrying out genetic studies for *ADA2* (formerly called *CECR1*). Serum ADA2 activity was low in all patients with the deficiency, while they are normal in healthy children and in classic PAN without mutation in *ADA2* [65].

Pathology: Pathologic features are related to the vasculopathy or vasculitis. The skin and central nervous system, but also gastrointestinal system, liver, renal, and coronary tissues are affected by the vasculopathy of small- and medium-sized arteries. Skin biopsy of livedoid rash shows infiltration with polymorphonuclear leukocytes and macrophages and perivascular T lymphocytes. There was no evidence of vasculitis seen in the biopsy materials. Skin biopsy of patients with cutaneous PAN revealed non-granulomatous, necrotizing arteritis of small- or medium-sized muscular arteries, histopathologically almost similar to classic PAN (Fig. 7).

Vasculopathy may also affect the liver, kidney, and other organs. Renal artery aneurysms and/or stenosis, lymphocytic infiltration, and glomerulosclerosis are reported. Biopsy from gastrointestinal lesions shows features of inflammatory bowel disease. Histopathologic examination of liver biopsies reveals nodular regenerative hyperplasia and/or periportal sclerosis. Intestinal necrosis, bowel perforation, stenosis, or aneurysms of the mesenteric or celiac arteries are also reported [65–67].

Treatment and Prognosis: Patients with deficiency of ADA2 respond poorly to conventional treatment for PAN. However, they show excellent

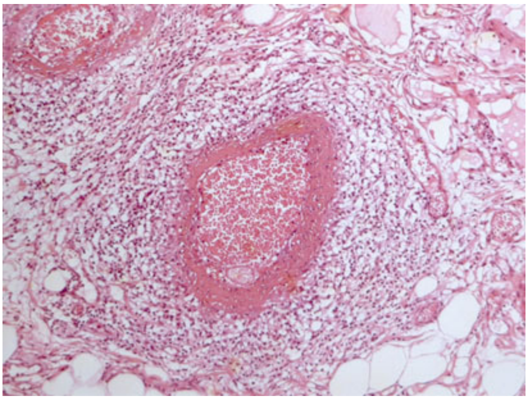

Fig. 7 Skin biopsy of a DADA2 patient showing similar microscopic appearance with PAN

response to anti-TNF drugs, in terms of successful control of fever, vasculopathy, and preventing cerebrovascular accidents [67, 69]. Patients with severe hematological involvement do not respond; hematopoietic stem cell transplant rescues hematological and immunological abnormalities [68].

Takayasu Arteritis

Takayasu arteritis is defined as a granulomatous inflammation of the aorta and its main branches [1, 2]. Although not confirmed, children seem to have a higher incidence of renal artery stenosis. This led to the inclusion of hypertension as a criterion to the new childhood criteria. According to the revised Ankara 2008 classification, *angiographic abnormalities* (conventional, CT or MR angiography of the aorta or its major branches and pulmonary arteries showing aneurysm/dilatation, narrowing, occlusion or thickened arterial wall (**mandatory**) plus one of five classifies the patient as having Takayasu arteritis [6]:

- Pulse deficit or claudication
- Four limb blood pressure discrepancy >10 mm Hg
- Bruits
- Hypertension (>95th percentile for age, sex and height)
- Elevated acute phase reactants

The etiology and pathogenesis are unknown, and the above features may include patients with renovascular hypertension due to fibromuscular dysplasia.

Clinical and laboratory features: General symptoms may occur. End-organ ischemic features ensue according to the involved vessel site. Relevant symptoms may be claudication, abdominal pain, headache, syncope, stroke, and renal hypertension due to renal artery involvement [2, 6, 70, 71]. Hypertension is the most common renal manifestation. Associated glomerulopathies have also been reported [72]. In adults, the disease is divided into pre-pulseless phase and a pulseless phase. The pre-pulseless disease is not always evident in children. Aorta and the large arteries on both sides of the diaphragm may be involved. Symptoms depend on the anatomical location of the artery and on the type of lesion (stenotic, occlusive, or aneurysmal) [6, 70].

Laboratory findings include high ESR and CRP [6]. Autoantibodies to nuclear antigens and ANCA are negative. The diagnosis depends on imaging techniques that demonstrate stenosis, and/or aneurysmal changes and/or arteritis involving the aorta and its branches. MR or CT angiography may provide evidence of Takayasu arteritis. These techniques provide information regarding thickening of the vessel wall that reflects inflammation [70]. Recent reports highlight the value of PET scan for the diagnosis. However, this scan is expensive and should be reserved for the rare instances where differential diagnoses of fibromuscular dysplasia pose a problem.

Pathology: Takayasu arteritis is a pan-arteritis, with initial inflammation being around vasa vasora and the medio-adventitial junction. A giant cell granulomatous reaction and laminar necrosis may be seen. Fragmentation of elastic fibers is prominent. Severe inflammation may lead to medial weakening, vascular dilatation, and aneurysm formation and reactive fibrosis. In the chronic phase, there is patchy mononuclear inflammatory infiltrate with medial scarring and vascularization (Fig. 8). Glomerulopathy is a rare complication [73–75].

Treatment and prognosis: Recently adult rheumatologists have published recommendations for

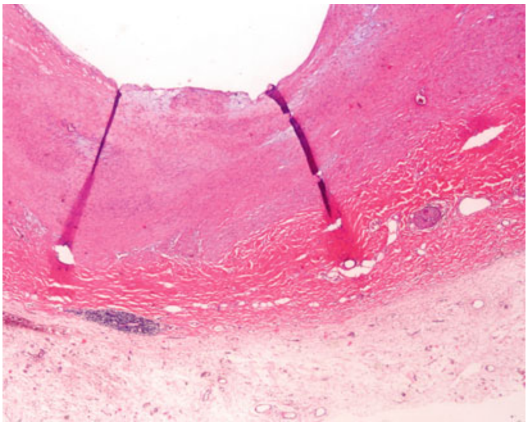

Fig. 8 TA. Chronic phase in thoracic aorta showing fibrosis in intima and fibrous thickening of the media

the treatment and management of large vessel vasculitis and Takayasu arteritis [76]. While there is lack of evidence-based data treatment in children, corticosteroids constitute the main treatment. We had suggested the use of cyclophosphamide for patients with life-threatening, severe involvement on both sides of the diaphragm, and methotrexate for limited disease [77].

Recently therapy with anti-TNF agents and tocilizumab has been reported to be effective in achieving clinical response in patients with Takayasu arteritis [78, 79].

For patients who require revascularization, both surgical and endovascular procedures can be performed, with low morbidity and mortality. The prognosis has improved with lower relapse rates. However, the evaluation of disease activity is a major problem in the management and follow-up. Any sign of vascular ischemia, rising ESR, and new angiographic abnormalities should suggest a relapse of the disease that requires appropriate management.

Behçet Disease

Behçet disease is classified according to the criteria used for adults where the presence of oral ulceration is mandatory. Two other criteria are required: genital ulceration, skin findings, eye involvement, and a positive pathergy test [80]. According to pediatric criteria, three of the following six are required to classify a patient as Behçet disease: oral aphthosis, genital ulceration, skin features, eye involvement, CNS involvement, and vascular involvement (venous thrombosis, arterial thrombosis, or arterial aneurysms) [81]. Behçet disease is a vasculitis that affects the mucosal membranes and the skin, just as Kawasaki disease. Epidemiology suggests spread through the ancient “silk road.” The disease is characterized by periods of exacerbations and remissions.

Behçet disease is rare in childhood with certain characteristics of interest. Behçet disease is the only vasculitis that affects vessels of all sizes and both arteries and veins, except systemic lupus erythematosus [1]. Behçet disease has a wide range of renal involvement, albeit rare [82]. Common glomerular lesions include crescentic GN, proliferative GN, and immunoglobulin A (IgA) nephropathy [82]. Aneurysms may be located throughout the renal artery, from the orifice of the main artery to intrarenal microaneurysms.

Pathology: Behçet disease has no strict pathognomonic features on histopathology, and wide spectrum of microscopic changes. Skin lesions show leukocytoclastic vasculitis and panniculitis with superficial and deep perivascular lymphocytes and neutrophils (Fig. 9) [80, 83]. Treatment depends on the organ system involved and frequently requires corticosteroids and immunosuppressive treatment. Adult rheumatologists have suggested recommendations for the treatment of BD [84].

In conclusion, kidney is an organ that is frequently involved in the vasculitides. It has a major impact on the morbidity of the disease. Careful assessment and effective management of these patients are essential. We await controlled, long-term studies to shape our evidence-based treatment in these children. We now have the classification criteria and the outcome assessments to guide us in our study designs. The Pediatric Vasculitis Assessment Score has been developed and validated for the use by pediatricians to assess treatment outcomes and evaluate the activity of disease in their patients. The pediatric community is ready for collaborative studies in childhood vasculitides.

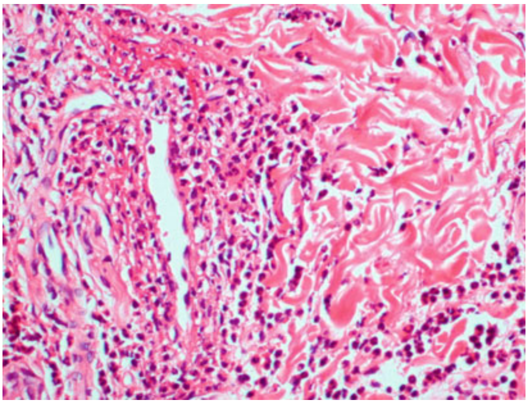

Fig. 9 Behçet's disease. Edema of the endothelial cells, fibrinoid degeneration, neutrophilic infiltration, and leukocytoclasis (destroyed leukocytes as nuclear dust) in cutaneous small vessel walls

Abstract

Childhood-onset systemic lupus erythematosus (cSLE) is a subset of SLE with onset prior to 16–18 years of age. Around 15% of patients with SLE present in childhood; patients with cSLE have a greater genetic component to their disease, more systemic involvement, and more severe disease course including higher risk for developing nephritis. Patients with cSLE develop loss of tolerance to self at an earlier time than patients with adult-onset SLE, or loss of tolerance progresses sooner to autoantibody production, immune complex deposition, and immune-mediated tissue injury. We review the diagnosis, classification criteria, and management of kidney disease in cSLE, by pediatric nephrologists and rheumatologists. Although the evidence basis for management often primarily relies on adult studies, there is growing literature on cSLE around the world. Fortunately, 5- and 10-year mortality is lower than in adult-onset SLE, and patient and renal survival has improved over the years. However, relapses are common, especially during the transition from adolescence to adulthood. Patients with cSLE also accrue organ damage and co-morbid conditions from lupus and their therapies, including cardiovascular, infectious, ocular, skeletal, growth, endocrine, and reproductive complications.

Introduction

Systemic lupus erythematosus (SLE) is a complex chronic autoimmune disease with multisystemic involvement characterized by the production of antibodies against self-antigens, immune complex formation, and immune dysregulation. Childhood-onset SLE (cSLE) accounts for 10–20% of SLE cases with an incidence of 0.3–0.9 per 100,000 and a prevalence of 3.3–24 per 100,000 [72]. Comparative studies have shown differences between cSLE and adult-onset SLE (aSLE). In a meta-analysis, cSLE was associated with severe clinical features particularly neurological involvement, renal involvement, oral ulcers, malar rash, vasculitis, fever, ocular, and hematological manifestations [27]. Children and adolescents with SLE have fulminant disease onset and course than adults with SLE, resulting in two to three times higher mortality [102].

cSLE has a strong female preponderance, with a female-to-male ratio 4:3, increasing to 9:1 during the reproductive years [102]. There is a difference in the ethnic composition of SLE in the world with higher frequency seen among African Americans, Asians, Hispanics, and Native Americans. In adults, non-Caucasian ethnicity has been identified as a risk factor for poor outcome [44] but in a study on cSLE, disease activity and damage were strongly associated with major organ disease independent of the patient's ethnicity. Non-Caucasians were significantly younger and more likely to have lupus nephritis [61].

The clinical phenotypes of SLE are heterogeneous; hence, manifestations are protean and variable. Classification criteria, established to identify a well-defined patient population suitable for research, are helpful in clinical practice. The classification of SLE, endorsed by the American College of Rheumatology (ACR) in 1982 [154] and revised later [63], has been most commonly applied. Due to low sensitivity in detecting early SLE, alternative classifications have been developed by the SLICC (Systemic Lupus International Collaborating Clinics) [120] and EULAR/ACR [6]. EULAR/ACR criteria total score $\geq$ 13, as opposed to the initially proposed score $\geq$ 10, most appropriately classifies cSLE [127]. In 2020, a kidney biopsy with lupus nephritis class III or IV and presence of a positive antinuclear antibodies (ANA) are deemed sufficient to classify a patient as SLE (Table 1).

Pathogenesis

Animal Models

The complexity and heterogeneity of the clinical presentation in SLE, combined to the inherent limitations of clinical research, have made it necessary to study various rodent models to dissect the cellular, genetic, and metabolic mechanisms of disease [90]. The major spontaneous models include the MRL/lpr, BXSB/Yaa, and (NZB x NZW)F1 models. In addition, lupus-like disease has been induced in rodents using pristane, nephrotoxic serum, and passive immunization with patient sera. MRL mice, carrying a pathologic variant named *lpr* in the FAS gene locus, develop lymphoproliferation due to a defect in apoptosis that ultimately leads to autoimmunity. Disease in the BXSB mouse strain is attributable to the Y-autoimmune accelerator (Yaa) locus, which duplicates 16 genes, including TLR7 (Toll-like receptor 7), an innate immune sensor encoded on the X chromosome that binds single-stranded RNA and activates type I interferon signaling. New Zealand white and black mice carry numerous gene variants predisposing to autoimmunity, but only F1 progeny develop tissue injury and immune complex glomerulonephritis (GN). Nephrotoxic serum (▶ Chap. 21, "Autoantibodies and Kidney Diseases") is generated in sheep or rabbits after immunization with purified mouse glomerular basement membrane (GBM). Injection of this serum into mice leads to inflammatory GN due to Fc-receptor-mediated recruitment of phagocytes binding immune complexes bound to GBM. These models have contributed major advances to the field, including numerous potential targets for pharmaceutical development. Each model shares specific subsets of attributes with SLE, and investigators evaluating novel agents need to select the animal model carefully [90].

Table 1 Classification criteria for systemic lupus erythematosus [6, 63, 120]

	ACR 1997 [63]	SLICC 2012 [120]	ACR/EULAR 2019 [6]

Genetics

Single gene defects or Mendelian-inherited associated with cSLE is very rare [37] (Table 2). Some mutations may affect several immune pathogenetic pathways: complement system, phagocytes oxidase system, apoptosis, nucleic acid repair, DNA degradation, DNA sensing, type I interferon, and B-cell development [37]. A variety of single mutations are associated with susceptibility to develop lupus nephritis.

The most frequent monogenic lupus is homozygous deficiency of early components of the classical complement pathway (C1q, C1r/s, C4, and C2) [70]. SLE or lupus-like manifestations have been detected in 81–90% of homozygous C1q deficient, 75% of homozygous C4-deficient, 65% of homozygous C1r/C1s deficient, and 10% of homozygous C2-deficient subjects [37]. Lupus nephritis has been described in 17–90% of these patients [37]. Complement deficiencies seem to predispose to SLE and lupus-like syndrome due to tolerance abnormalities, aberrant apoptotic bodies clearance and poor clearance of immune complexes, perpetuating and intensifying the immune response. Non-cleared debris would operate as antigens to stimulate helper T cells and production of multiple autoantibodies [142].

A set of genes associated with monogenic lupus showed systemic autoimmunity and was associated with lupus phenotype. Lupus nephritis was reported in 30–100%, mainly with mutations in the following: *PRKCD, C1QA, C1QB, C1QC, C1R, C1S*, and *C4* [37]. Genetic analysis (whole exome sequencing) should be indicated for SLE or lupus-like patients with early onset of clinical features (<6 year), parental consanguinity, family history for autoimmune condition in a first-degree relative, and severe disease with tissue scaring [70].

Environment

Epidemiologic evidence exists for association of silica, Epstein-Barr infection, and cigarette smoking with SLE [15]. Alcohol consumption is associated with decreased SLE risk. There are conflicting data associating infections, vaccinations, air pollution, ultraviolet (UV) light, solvents, pesticides, and heavy metals, for example mercury. The hydrocarbon pristane, a component of mineral oil, is used to model lupus in mice [90]. While UV radiation exposure is known to exacerbate preexisting lupus, it is unclear whether this is a risk factor for its development. Biologic mechanisms linking environmental exposures and SLE include oxidative stress, systemic inflammation, cytokine upregulation, and molecular mimicry to viral antigens. Alterations in the gut microbiome include impaired gut-barrier function, expansion of *Proteobacteria*, reduction of *Firmicutes* spp., and inverse association between disease activity and diversity of microbiota [143]. Development of antibodies against *Ruminococcus gnavus* correlate with double-stranded (ds) DNA antibodies and progression to lupus nephritis.

The environment has been proposed to interact at the epigenetic level in lupus [13]. UV exposure is associated with reduced DNA methyltransferase 1 expression in patients with SLE. Dietary content of transmethylation micronutrients (betaine, methionine, and choline as methyl donors; zinc, folate, and B-vitamins as methyl cofactors) correspond with the severity of lupus in rodent models. Flares in lupus may be linked to epigenetic disequilibrium. While there is decreased DNA methylation of CpG islands at type-1 interferon genes and other susceptibility loci in active lupus, there is increased methylation of genes required for regulatory T-cell function.

Hormonal Factors

Strong epidemiologic evidence supports associations of oral contraceptives, early age at menarche, postmenopausal hormone therapy, and endometriosis with increased risk of SLE [15]. Female sex is a strongly predisposing factor, and the overwhelming majority of cases occur among women during

Table 2 Monogenic conditions associated with systemic lupus erythematosus (SLE)

Disease	Gene mutated	Inheritance	Clinical features of lupus	Non-SLE features
Aicardi Goutières syndrome	*TREX1*	AD or AR*	Early-onset; chilblain lupus	Encephalopathy, intracerebral calcification
	RNASAH2A/B/C	AD		
	ADAR1	AD		
	SAMHD1	AR		
	IFIH1	AD		
STING (stimulator of interferon genes deficiency)	*TMEM173*	AD	Chilblain lupus; interstitial lung disease	Vasculopathy with onset in infancy
SPENCDI (spondyloenchondrodysplasia with immune dysregulation)	*ACP5*	AR	Early-onset (frequent LN, cytopenia)	Osseous dysplasia short stature
DNase 1 deficiency	*DNASE1*	AD	Adolescent onset, dsDNA(+)	–
DNase 1 IL3 deficiency	*DNASE1L3*	AR	Early-onset illness, nephritis, ANCA(+)	Hypocomplementemic urticarial vasculitis
PKCδ deficiency	*PRKCD*	AR	Early-onset	Lymphoproliferation
C1q deficiency	*C1QA/B/C*	AR	Early-onset; nephritis, CNS, and photosensitivity common	Susceptibility to encapsulated bacterial infections
C1r/C1s deficiency	*C1R/C1S*	AR	Early-onset, nephritis frequent	
C2 deficiency	*C2*	AR	Photosensitivity and arthritis; nephritis: mild or absent	
C3 deficiency	*C3*	AR	Malar rash, photosensitivity, arthralgia, Raynaud	
C4 deficiency	*C4A/B*	AR	Organ involvement, nephritis	
Chronic granulomatosis Disease	*CYBB*	X-linked	Discoid lupus	Susceptibility to pyogenic, fungal infections
	NCF1/2	AR		

*abbreviations: *AD* autosomal dominant, *AR* autosomal recessive

childbearing years. Both sex hormones and X chromosome factors are thought to be responsible. Individuals with Klinefelter syndrome (47,XXY) also have increased incidence of SLE. Epigenetic modification of genes on the inactive X chromosome has been proposed as a possible mechanism [132]. In a meta-analysis, significantly lower testosterone and dehydroepiandrosterone, and higher estradiol and prolactin are seen in women with SLE [99]. Data on menstrual irregularity, breastfeeding duration, number of ovulatory years, and parity have been inconsistent.

Immune Complexes (Antibody-Mediated Immunity)

SLE is characterized by loss of tolerance (▶ Chap. 21, "Autoantibodies and Kidney Diseases") to numerous self-antigens, although no one unifying event has been identified. Many patients show defective clearance of cell debris, which triggers autoimmune responses against large intracellular antigens (chromatin, nucleosomes, DNA, RNA, and ribonuclear proteins) that would otherwise evade immune responses.

Others demonstrate increased circulating levels of extracellular vesicles, which are membrane-bound microparticles, exosomes, or apoptotic bodies containing phospholipids and nuclear or mitochondrial debris. Defects in the classical pathway of complement (such as C1q), DNase enzymes, and phagocyte receptors (encoded by *FCGR2B*, *FCGR3*, *ITGAM*) contribute to an increased exposure to extracellular vesicles [37].

In SLE, although autoantibodies can be detected against nearly any portion of the human proteome, the most common antibodies detected are antinuclear antibodies (ANA). However, individuals can test positive for ANA without developing manifestations of SLE. Numerous assays can be used to profile ANA reactivity; specificity for anti-double stranded DNA or Smith antigen is more in patients with SLE.

Immune complexes form when antibodies bind to their specific antigen. Circulating immune complexes form against antigens in the blood or extracellular fluid, and can deposit in vascular capillary beds anywhere in the body. In situ immune complex formation occurs when autoantibodies bind to their antigen on cell surfaces or extracellular matrix. In situ immune complexes can also form against circulating antigens that are trapped in necrotic tissue, basement membranes, or cellular glycocalyces. Immune complexes can also become quite large and deposit on tissues. Fixed deposits are immune deposits that remain visible after tissue processing for viewing by electron microscopy. Although immune complex formation can be helpful in opsonization and clearance of foreign or toxic substances, abundant immune complexes can lead to inflammation by leukocytes via binding to Fc-receptors [121].

Innate Immunity

Patients with cSLE have increased numbers of the low-density granulocyte subset of neutrophils [101]. The production of neutrophil extracellular traps (NETs) has been shown to be important in the pathogenesis [94]. NETosis in response to immune complex binding to neutrophils can propagate immune injury and further expose nuclear antigens to circulating autoantibodies.

The type-I interferon pathway has also proven to be pathogenic in many patients with SLE. Administration of recombinant human IFN to treat viral infections and malignancies has resulted in de novo cases of lupus, and disease improved with cessation of therapy [111]. The disease genes TLR7 and TLR9 encode intracellular receptors for nucleic acids. TLR activation leads to production of type-I interferon as part of the innate immune response. Polymorphisms of *IRF5*, *IKZF1*, and *STAT4* are all linked to development of immune complex GN and their encoded proteins all mediate type-I interferon signaling in inflammatory cells as well as resident kidney cells [39]. Defects in other disease genes that regulate another innate immune response, the nuclear factor kappa-B pathway (*TNFAIP3*, *TNIP3*), also predispose to development of autoimmune nephritis. Hypocomplementemia is due to consumption of complement proteins, mostly due to classical pathway activation (▶ Chap. 22, "Membranoproliferative Glomerulonephritis and C3 Glomerulopathy in Children") by immune complexes.

Lymphocytes (Cell-Mediated Immunity)

The loss of tolerance to self-antigens in SLE can also be caused by abnormalities in lymphocytes. The risk variant for *PTPN22* produces a mutant signaling protein that leads to failure to eliminate autoreactive B cells [100]. Reduced expression of BLK, another B-cell signaling molecule, promotes nephritogenic lymphocyte generation in mice prone to lupus [136]. BAFF (B-cell activating factor) promotes the humoral immune responses that then sustain autoantibody production [19].

In addition to providing T cell help to autoreactive B cells, tissue injury in SLE can occur by direct T-cell-mediated cytotoxicity [38]. Follicular helper CD4 cells drive the formation of antibody secreting cells. Type 17 T-helper cells produce IL-17 and promote inflammation and humoral immunity. Cytotoxic CD8+ T cells release granzymes and perforin to lyse cellular targets. Unique to patients with SLE, double negative (CD3+, CD4–, CD8–) T cells escape negative selection and promote inflammation. Regulatory T cells are produced to suppress effector T-cell responses, but can become dysregulated in SLE [38].

Pathogenesis of Nephritis

Tissue damage in multiple organs requires more than just autoantibody generation. Experimentally, anti-dsDNA and anti-nucleosome antibodies can deposit in the kidney and cause proteinuria [82]. Besides ANA, autoantibodies against alpha-actinin, alpha-enolase, annexin A1, and vimentin in the kidney associate with GN. Anti-C1q antibodies occur at higher titers in patients with LN and co-localize with complement deposits in their glomeruli [157]. However, experimentally and clinically, immune complex deposition in the kidney can be detected in the absence of histopathology or clinical disease.

It is not clear why only certain children with SLE develop nephritis. CC-chemokine ligand 2/monocyte chemoattractant protein-1 (CCL2/MCP-1) is involved early in the GN process [4], and tumor necrosis factor is involved at onset of proteinuria. Type-I interferons cause direct injury to cells in the glomerulus. Genetic polymorphisms in the *KLK* locus with decreased renal concentrations of kallikrein also associate with the development of nephritis. Numerous inflammatory cells play a role in pathogenesis of nephritis [4]. Neutrophil and endothelial cell microparticles contribute to immune complex formation and localize to glomerular immune deposits. Resident and infiltrating macrophages and dendritic cells participate in inflammation and development of kidney fibrosis.

Cellular infiltrates in lupus nephritis are common and are composed of phagocytes and B and T lymphocytes [30]. T-cell subsets, including cytotoxic CD8 cells, type 17 T-helper CD4 (TH17) cells, follicular helper CD4 (TFH) cells, and double negative TH cells, have all been implicated. Effector T cells, together with numerous soluble mediators, elicit chronic inflammation within the glomeruli and tubulointerstitium.

Immune complexes may bind directly to glomerular mesangial [137] and endothelial cells [152]. In mesangial cells, binding to Fc-receptors causes complex internalization, cellular proliferation, and release of inflammatory cytokines [121, 152]. Moreover, mesangial cells produce more extracellular matrix after treatment with anti-dsDNA antibodies. Anti-dsDNA antibodies also bind to annexin II on mesangial cells with functional responses [172].

Clinical Manifestations

SLE can present with intermittent or persistent symptoms, single or multiple organ involvement, and most often with constitutional symptoms of fever (51%), malaise, anorexia, and weight loss. Main clinical features are mucocutaneous involvement (80–96%), arthritis (82%), kidney manifestations (50%), and hematologic features (43–46%), with an unpredictable natural history. In general, children with SLE have more severe disease than their adult counterparts, with more organ involvement, more laboratory abnormalities, and requiring frequent use of immunosuppressive agents [150].

Kidney Involvement

Approximately half of children with SLE develop kidney involvement at one point in their disease course. Frothy or tea-colored urine, edema, anasarca, and hypertension, which may or may not be associated with increased creatinine levels, are the most common manifestations of childhood LN. Eighty to 90% of childhood lupus nephritis develops within the first year of diagnosis and is a significant cause of morbidity and mortality across all ages. Between 10 and 30% progress to kidney failure within 15 years [125].

Disease manifestations and outcomes particularly are heterogeneous. The American College of Rheumatology (ACR) 1997 revised classification criteria for SLE described kidney involvement as persistent proteinuria >0.5 g per day, or greater than 3+ if quantitation is not performed, or presence of granular casts which may be red blood cell, hemoglobin, tubular, or granular casts, or mixed. A similar criterion is stated by the SLICC classification criteria, urine-protein-to-creatinine ratio, or urine protein representing 500 mg protein/24 h, and histopathologic findings of lupus nephritis [58]. The 2019 European League Against Rheumatism (EULAR)/ACR criteria for SLE defines proteinuria as above [6], and follows the lupus nephritis classification of the 2003 criteria of the International Society of Nephrology/Renal Pathology Society (ISN/RPS).

Urine sediment analysis helps distinguish proliferative from non-proliferative forms of kidney involvement. When >50% of affected glomeruli have hypercellularity, necrosis, or large (hyaline) deposits, the clinical symptoms are more severe, with active urine sediment, nephrotic syndrome, hypertension, and AKI/CKD. Other forms of renal involvement include tubulointerstitial nephritis, thrombotic microangiopathy (TMA; Renal Involvement in Children with Hemolytic Uremic Syndrome (HUS) and Thrombotic tHROMBOCYTOPENIC Purpura (TTP)), noninflammatory necrotizing lupus vasculopathy, and lupus vasculitis (▶ Chap. 19, “Renal Vasculitis”).

Extrarenal Manifestations

Mucocutaneous

Skin manifestations of lupus are common and may be the first sign of disease. The lesions can be classified as acute, subacute, or chronic. The butterfly or malar rash is an acute violaceous or pink, non-scarring, photosensitive rash crossing the nasal bridge and sparing the nasolabial folds. Subacute lesions are annular violaceous to red scaly plaques that can erupt on extremities and are non-scarring as well. Rashes that are chronic are scarring and usually involve the scalp, V-region of the neck, and face. The other chronic lesions of lupus include panniculitis and chilblains.

Nonspecific cutaneous symptoms of lupus can be related to vasculitis and vasculopathy associated to lupus. Purpura and urticarial vasculitis are examples of the former, while livedo reticularis, thrombophlebitis, and Raynaud phenomenon represent the latter. Alopecia of lupus is diffuse, non-scarring hair loss, although it can also be patchy. Single or multiple ulcerations of the oral, gingival, and nasal mucosa characterize active disease [7].

Musculoskeletal

Joint and muscle symptoms of lupus are present in approximately 50% of patients. Arthralgia is a common complaint. Oligo- or polyarthritis associated with morning stiffness is non-deforming and involves both the large and small joints. Tendinitis and tenosynovitis can be painful and disabling. Approximately 5% patients with musculoskeletal involvement have myositis [135].

Nervous System

Neuropsychiatric lupus is more frequent in cSLE than in adult onset SLE. It can affect the central, peripheral, and autonomic nervous systems and can result in headaches, acute confusional states, seizures, psychosis, cognitive deficits/dysfunction, chorea, cerebrovascular accident, cranial nerve palsies, mood disorder/depression, movement disorder, aseptic meningitis, demyelinating syndrome, myelopathy, dysautonomia, and pseudotumor cerebri. Headache is the chief symptom (80–90%), and may be sometimes accompanied by seizures [146].

Cardiovascular

Similar to neuropsychiatric symptoms, cardiovascular manifestations are more common and more severe in children than in adults. These include chest pain, pericardial effusion, valvular disease pericarditis, and cardiac failure; the most frequent vascular manifestations are vasculitis and thromboembolism. SLE is independently associated with a higher likelihood of having pericarditis or myocarditis. SLE may present with Libman-Sacks endocarditis, an aseptic endocarditis commonly affecting the mitral valve. It is rare and is best evaluated by trans-esophageal echocardiogram [80]. Acute cardiac and vascular manifestations of SLE are associated with significant mortality; however, chronic cardiovascular effects of SLE are a burden as children survive into adulthood. About 36% of the cardiac complications of SLE are silent [57].

Pulmonary

Pulmonary involvement occurs in 40% of cSLE within the first year of diagnosis and doubles at any point during the disease course. Cough is a common complaint; recurrent or persistent coughing is an indication of several respiratory disorders or complications related to lupus, with pleuritis, with or without unilateral or bilateral effusion, being the most common [124]. Acute lupus pneumonitis and alveolar hemorrhage are rare entities, and associated with grave outcomes. Dyspnea, hypoxemia, and falling hematocrit heralds diffuse alveolar hemorrhage [144].

Asymptomatic or subclinical pulmonary abnormalities are present in a significant number of cSLE patients through spirometry or DLCO, including airway defects in 50%. Pulmonary hypertension and interstitial lung disease, the latter presenting with exertional dyspnea and pleuritic pain, are among the chronic pulmonary complications of cSLE. Pulmonary hypertension can be associated with signs of right heart failure [124].

Gastrointestinal

The most frequent gastrointestinal symptom in cSLE is abdominal pain, followed by diarrhea, and jaundice. Findings of ascites, peritonitis, gastritis, enteritis, colitis, and hepatomegaly are also documented [148]. Transaminitis may occur due to lupus activity, or a consequence of treatment. Autoimmune hepatitis associated with lupus is a progressive inflammatory liver disease and can coexist with cirrhosis and cholangitis. Diagnosis of lupus enteritis, a rare disease entity, is made on computed tomography findings of dilated bowels and bowel wall thickening [148].

Hematologic and Reticuloendothelial System

SLE can affect at least one hematopoietic lineage, leading to anemia, leukopenia, lymphopenia, and thrombocytopenia [135]. The decrease in hemoglobin can be attributed to anemia of chronic disease, iron deficiency, or hemolysis. Autoimmune hemolytic anemia, defined as hemoglobin <10 g/dL and reticulocytosis or a positive Coombs test, is more common, severe, and likely to be associated with hepatosplenomegaly in cSLE than in adult-onset SLE. Leukopenia and thrombocytopenia are common as well and usually mild. While there is no evidence of a significant association between overall reduction of white blood cell count and infection, lymphopenia and neutropenia are strongly associated with the risk of major infections. Thrombocytopenia, similar to anemia, is chiefly autoimmune in nature, and may be related to antiphospholipid syndrome (aPLS) [68].

Splenomegaly and lymphadenopathy may be seen in active disease; prolonged duration of disease may result in splenic atrophy in cSLE. Kikuchi-Fujimoto disease, or histiocytic necrotizing lymphadenitis, is a rare disorder outstandingly associated with SLE [149].

Endocrine

Patients with cSLE can exhibit hypothyroidism or hyperthyroidism. Hashimoto thyroiditis is the most common autoimmune thyroid disease at any age, most frequently age at adolescence. It often manifests as hypothyroidism, is linked to thyroid peroxidase and thyroglobulin antibodies, and is associated with connective tissue diseases [91]. Hyperglycemia is usually transient; however, diabetes mellitus type 2 may develop with long-term high dose corticosteroid treatment [59]. Diabetes type 1, on the other hand, may precede or follow lupus diagnosis as part of polyautoimmunity, as in Hashimoto thyroiditis and autoimmune hepatitis [140]. Adrenal insufficiency may occur with aPLS, unusual stress, or abrupt corticosteroid withdrawal [83].

Ocular

Eye irritation or itchiness due to dryness is common (40%). Gradual or sudden blurring of vision is of concern, and although causes such as retinal vein or artery occlusion and uveitis (5%) are rare, the outcomes may be serious. Findings in lupus retinopathy include cotton wools spots, intraretinal hemorrhages, and vascular tortuosity

[47]. Patients with cSLE should be monitored for medication-related damage, particularly retinal toxicity and cataracts secondary to long-term intake of hydroxychloroquine and steroids, respectively [59].

Drug-Induced Lupus

Approximately 10% of SLE cases are drug-induced lupus [169]. This spectrum includes clinical features and laboratory abnormalities of SLE with persistent drug exposure, and generally lacking of severe SLE complications [160]. The most frequent medications associated with lupus include antiarrhythmic (procainamide, quinidine), antihypertensive (hydralazine), antimicrobial (minocycline), anticonvulsant (carbamazepine, phenytoin), and TNFα blockers (infliximab, adalimumab, etanercept) [160]. The highest risks of drug-induced lupus are associated with use of procainamide (15–20%) and hydralazine (8–13%).

Clinical features of lupus occur several weeks, months to years after drug exposure, and improve after discontinuation of the putative drug. The clinical involvement of drug-induced lupus includes mainly mild to moderate disease features, such as fever, fatigue, myalgia, arthralgia, arthritis, serositis, sicca syndrome, and Raynaud phenomenon [160]. The most frequent drug-induced skin manifestation is subacute cutaneous lupus, with rare cases reported of chronic lupus, as discoid lupus. Lupus nephritis, neuropsychiatric, hematologic abnormalities, and hypocomplementemia are rarely described [160].

ANA have been observed in 90–100% of patients with drug-induced lupus [160], particularly with homogeneous immune-staining. Anti-histone antibodies are characteristic of drug-induced lupus, identified in 90–95% of patients [160], specifically directing the (H2A-H2B)-DNA complex. Anti-dsDNA and anti-Sm antibodies are rarely observed in drug-induced lupus.

Neonatal Lupus

Neonatal lupus arises from the passive placental transfer of pathogenic maternal autoantibodies to SSA (Ro) or SSB (La). It occurs in up to 2% of offspring to mothers with these antibodies irrespective of maternal history of autoimmune disease. Clinical manifestations include cardiac, cutaneous, hematologic and hepatic, with cardiac complications being the most serious. Conduction system abnormalities including congenital heart block is estimated to occur in 1 in 15,000 to 1 in 22,000 live births independent of any structural abnormalities of the heart [28]. The risk of cardiac neonatal lupus in subsequent pregnancies in mothers with a previously affected child is 17% [93]. Congenital heart block portends a significant mortality in 20 to 30% of neonates, with 67% of affected survivors requiring pacemaker implantation.

The rash of cutaneous lupus is located primarily on the scalp and periorbital area, and is induced and exacerbated by exposure to ultraviolet light. It spontaneously resolves as maternal antibodies are cleared from the neonatal circulation by 6–8 months of age. Hematologic findings include anemia, thrombocytopenia, and neutropenia. Hepatobiliary manifestations occur in 10–25% of patients and include elevation in transaminases, cholestasis, or liver failure. In a series of 50 infants born to mothers with anti-SSA/Ro antibodies who themselves were positive for the same antibodies, gradual decrease of antibodies occurred simultaneously with disappearance of noncardiac features. At 9 months of life, only 10% had persistent antibodies [175].

Antiphospholipid Syndrome (aPLS)

Childhood-onset SLE has a high prevalence of antiphospholipid antibodies, resulting in high risk of thrombosis. Pediatric aPLS (▶ Chap. 21, "Autoantibodies and Kidney Diseases") is characterized by one or more clinical episodes of arterial, venous or small-vessel thrombosis, in any tissue or organ, and the presence of at least one antiphospholipid antibody: anti-cardiolipin (IgG, IgM), lupus anticoagulant, and anti-β2 glycoprotein-I (IgG, IgM) [11].

Primary aPLS occurs in patients without any signs or symptom of autoimmune diseases. Secondary aPLS is associated with autoimmune disease or other acute or chronic disease, especially cSLE and lupus like disease [11]. A recent multicenter study on 1512 cSLE patients described cumulative aPLS in 4%. Autoimmune thrombosis was diagnosed at disease onset in 58% patients

[68]. Venous and arterial thromboses are the main sites of thrombotic manifestations in cSLE-related APS [68]. Non-thrombotic manifestations associated with cSLE-APS occurred in 31%, mainly livedo reticularis in 21%, valvar thickening in 6%, and valvar vegetations not related to infections in 3% [68]. Pregnancy morbidity has been infrequently reported in adolescents (1–3%) [68]. Autoimmune thrombosis involving kidneys has been rarely reported. An international registry revealed that thrombotic microangiopathy involving the kidneys occurred in 2% of pediatric patients with aPLS at disease onset, renal vein thrombosis was observed in 1%, and renal arterial thrombosis in 1% [11].

Pediatric catastrophic antiphospholipid syndrome (CAPS) is defined as severe multiorgan thrombosis developing over a short time period, and can occur in children with SLE [18]. Kidney involvement is present in 63% of episodes of pediatric CAPS, and includes kidney failure (48%), arterial hypertension (24%), and proteinuria (13%). Approximately, 25% patients die at the moment of the catastrophic event [18].

Kidney Biopsy, Pathology

Kidney biopsy is the gold standard for the diagnosis of lupus nephritis. Practice patterns for initial and repeat kidney biopsy have been published for cSLE [166]. Most specialists use the indications for initial kidney biopsy developed by the American College of Rheumatology (Table 3) [56], whereas others use more inclusive indications.

Histological Classification

The kidney pathology (▶ Chap. 7, "Technical Aspects of Renal Pathology". Alternatively, we could include a figure with representative histopathology of all 6 classes, as in 7th edition) seen in SLE patients varies widely. As in adult onset SLE, either the World Health Organization classification, revised last in 1995 [33], or the International Society of Nephrology/Renal Pathology Society (ISN/RPS) classification, revised in 2018 [12], is used to classify the histological findings (Table 4). The prevalence for each lupus nephritis class is similar in cSLE and adult onset SLE [20]. The utility of distinguishing between histological classes, such as proliferative, and membranous lupus is supported by studies of SLE in children [173].

Although clinical presentation can predict histological findings in lupus nephritis, exceptions are common. Isolated asymptomatic hematuria and/or mild proteinuria are seen in lupus nephritis class I or II. Proliferative lupus nephritis often presents with the acute nephritic syndrome, defined by hematuria (microscopic or macroscopic), accompanied by hypertension and proteinuria (mild to nephrotic-range) (▶ Chap. 8, "Approach to the Child with Hematuria and/or Proteinuria"). In lupus nephritis class IV, symptoms are similar to class III, but with higher risk for progression to kidney failure. Class V (membranous) disease usually presents with isolated nephrotic syndrome. Some patients show presence of mixed proliferative and membranous lesions. Over time, the class of lupus nephritis can change, especially with disease flares.

Activity and Chronicity

Active lesions are amenable to immunosuppressant therapy, while chronic lesions represent nonreversible damage [12], requiring supportive therapy. Activity index and chronicity index quantify mainly glomerular injury (Table 5), and tubulointerstitial activity index quantifies extra-glomerular disease [60]. As in adults, risk factors for poor outcome in cSLE include activity index ≥ 7, chronicity index ≥ 4, and tubulointerstitial activity index >5 [24, 174]. Fibrinoid necrosis and cellular/ fibrocellular crescents are weighted as they historically associate with higher rates of long-term kidney failure. The activity and chronicity indices may not reflect the severity of lupus nephritis, and may not respond to therapy at the same rates as clinical and laboratory findings.

Table 3 American College of Rheumatology (ACR) guidelines on indications for first kidney biopsy

Increasing serum creatinine, without compelling alternative causes (such as sepsis, hypovolemia, or medication)
Confirmed proteinuria ≥ 1.0 g/24 h, or spot urine protein-to-creatinine ratio (uPCR) ≥ 1.0 mg/mg
Combination of: [i] proteinuria ≥ 0.5 g/24 h (or uPCR ≥ 0.5 mg/mg) plus [ii] hematuria ≥ 5 RBC per hpf, confirmed in ≥ 2 tests done within a short period of time, without compelling alternative causes
Combination of: [i] proteinuria ≥ 0.5 g/24 h (or uPCR ≥ 0.5 mg/mg) plus [ii] cellular casts, confirmed in ≥ 2 tests done within a short period of time, without compelling alternative cause (such as UTI, or menstruation)

Table 4 Revised 1995 World Health Organization (WHO) and 2018 Revised International Society of Nephrology/Renal Pathology Society (ISN/RPS) classification of lupus nephritis [12, 33]

CLASS[b]	WHO 1995	ISN/RPS 2018
I	**Minimal change GN**[a]	**Minimal mesangial lupus nephritis** (mesangial immune deposits by IF or EM; normal by light microscopy)
II	**Mesangial GN**	**Mesangial lupus nephritis** (mesangial hypercellularity; no influx of leukocytes)
III	**Focal segmental GN** (proliferative, sclerotic lesions involving <50% of glomeruli)	**Focal lupus nephritis** (mesangial and capillary influx of leukocytes, or endocapillary wall immune deposits, involving <50% of glomeruli)
IV	**Diffuse proliferative GN** (DPGN, lesions involve >50% of glomeruli)	**Diffuse lupus nephritis** (mesangial and capillary influx of leukocytes, or endocapillary wall immune deposits, involving >50% of glomeruli)
V	**Membranous GN**, isolated (Va) or mixed with mesangial lesions (Vb)	**Membranous lupus nephritis** (sub-epithelial immune deposits without influx of leukocytes)
VI		**Advanced sclerosing lupus nephritis** (>90% glomerular sclerosis without active lesions)

[a] abbreviations: EM electron microscopy; GN glomerulonephritis; IF immunofluorescence
[b] Non-classifiable forms of lupus include lupus podocytopathy, pauci-immune renal vasculitis, renal thrombotic microangiopathy (TMA), and renal antiphospholipid syndrome (aPLS)

Table 5 Revised 2018 International Society of Nephrology/Renal Pathology Society (ISN/RPS) scoring system for disease activity and damage on kidney biopsy [12]

Activity index	Score[a]	Chronicity index	Score[a]
Endocapillary hypercellularity	0–3	Glomerulosclerosis	0–3
Glomerular neutrophils/karyorrhexis	0–3	Fibrous crescents	0–3
Fibrinoid necrosis	(0–3) × 2	Tubular atrophy	0–3
Hyaline deposits	0–3	Interstitial fibrosis	0–3
Cellular, fibrocellular crescents	(0–3) × 2		
Interstitial inflammation	0–3		
Total	0–24	Total	0–12

[a] Scoring of each criteria based on a 4-point scale: absent, mild, moderate, severe based on involvement of 0%, 1–25%, 25–50%, and >50%, respectively

Non-classifiable Kidney Manifestations

Some patients with SLE develop kidney disease that is not primarily caused by immune complex deposition. Lupus podocytopathy has been reported in 1% patients with adult onset SLE with kidney involvement [67]. These patients present with nephrotic syndrome; histology shows minimal change or focal segmental glomerulosclerosis (FSGS) with >50% podocyte foot process effacement on electron microscopy. The response to corticosteroids was inconsistent in patients with FSGS, but isolated lupus podocytopathy with minimal change histology tends to respond well to therapy with corticosteroids, with overall response rates of 95% at

12 weeks and complete response in 75%. As with podocytopathies in patients without SLE, relapse rates are high.

Pauci-immune lupus nephritis, with segmental necrotizing GN, has been described in SLE with class III-like histology, except that there was a paucity of immunostaining for immunoglobulin or complement, and paucity of electron dense deposits [138]. These patients are less likely to have hypocomplementemia or dsDNA antibodies, and more likely to present with AKI. Anti-neutrophil cytoplasmic antibodies (ANCA) are not specific for pauci-immune LN, but may be pathogenic in these patients. The prevalence of this overlap histology is low, at ~2% of all patients with lupus nephritis. Remission is reported in 50% patients, but renal and patient survival is worse than for class IV diffuse proliferative GN [69].

In inflammatory lupus nephritis, coincident microangiopathy often responds well to immunosuppressive medications. For isolated renal aPLS (▶ Chap. 21, "Autoantibodies and Kidney Diseases"), anticoagulation can be considered, especially when presenting with AKI. The diagnosis and management of isolated renal thrombotic microangiopathy (TMA) (Renal Involvement in Children with Hemolytic Uremic Syndrome (HUS) and Thrombotic Thrombocytopenic Purpura (TTP)) is similar to atypical hemolytic uremic syndrome in patients without SLE.

Indications for Repeat Biopsy

Nephritic flares often warrant repeat biopsy to evaluate for proliferative lupus nephritis, especially when accompanied by high serum creatinine. Proteinuric flares are usually managed with an increase in the dose of either corticosteroids or maintenance immunosuppression, and a repeat biopsy is rarely necessary. Class change in lupus nephritis is commonly seen. The scenario to avoid is the patient with non-proliferative class or low activity index on initial biopsy who develops a kidney flare with undetected proliferative class or high activity [166]. Under-treatment of such patients can lead to non-responsiveness and kidney failure.

Laboratory Investigations

Multisystem involvement in cSLE necessitates a number of laboratory tests and ancillary procedures. The investigations are done primarily for diagnosis, as well as to monitor disease activity, response to therapy, adverse effects from medications, and guide to prognosis.

Urinalysis

Urinalysis is mandatory at baseline and periodically to examine for proteinuria, hematuria, and cylindruria. Urine protein-creatinine ratios (spot, 24-hour collection) are required for monitoring response to therapy [167].

Immunologic Studies

The most important are the serologic tests that detect antibody and complement levels. SLE is characterized by positivity of autoantibodies, the hallmark of which is ANA. ANA is used as a screening test; at a titer of 1:80 by immunofluorescence assay, it has an estimated sensitivity and specificity of 97.8% and 74.7%, respectively [85]. Although up to 33% of healthy children may have test positive to ANA, it is the best discriminator between children with SLE and those without chronic inflammatory disease. ANA pattern can be homogenous, diffuse, peripheral, speckled, nucleolar, or centromere. While all patterns are associated with SLE in different degrees, each pattern may also be associated with other autoimmune diseases. A homogeneous pattern is consistent with antibodies to native DNA and is commonly associated with SLE. The peripheral pattern, strongly associated with SLE, can be positive in autoimmune liver disease and Sjogren syndrome. Mixed connective tissue disease, scleroderma, overlap syndrome, and dermatomyositis exhibit a speckled, nucleolar, or centromere pattern.

Confirming the diagnosis of SLE in both children and adults requires further antibody testing. Anti-dsDNA antibodies are specific to SLE, associated with a homogeneous or peripheral ANA pattern, and predict active nephritis. Another specific, although poorly sensitive, lupus autoantibody is anti-Smith (Sm). It is associated with a speckled ANA pattern. Anti-ribonucleoprotein (RNP) is a nonspecific antibody, which when present in high titers is associated with mixed connective tissue disease. Anti-Ro/SSA and anti-La/SSB are characteristic of Sjogren syndrome and neonatal lupus [156].

Antiphospholipid antibodies (aPLs) are detected in about 30% patients with cSLE, significantly lower than in adults. The most important aPLs are anti-cardiolipin, lupus anticoagulant, and β2-glycoprotein-I antibodies. Presence of lupus anticoagulant causes prolonged aPTT. Anti-cardiolipin and β2-glycoprotein-I antibodies have three subcomponents, IgG, IgA, and IgM, with IgG being the most important clinically. Antiphospholipid syndrome is characterized by recurrent arterial or venous thrombotic events and complications during pregnancy. Trauma, surgical procedures, and infections may transiently cause positive aPLs.

Complement levels have been used as markers of disease activity; hypocomplementemia often signify active lupus especially lupus nephritis. The complement system appears to have protective features in that hereditary homozygous deficiencies of the classical pathway components, such as C1q and C4, are associated with increased risk for SLE [37]. Hence, it may be difficult to know whether the low complement is due to consumption or from inherited deficiencies of one or more alleles.

Extrarenal Manifestations

Laboratory evaluation of cSLE should include determination of acute phase reactants, complete blood count, and biochemical profile. Erythrocyte sedimentation rate and C-reactive protein are indirect parameters of inflammation and can be useful in differentiating lupus flare from infection. Complete blood count is advised to screen for potential cytopenias; anemia must be evaluated with peripheral smear, reticulocyte count, iron studies, and Coombs test. A chemistry panel will evaluate electrolytes, transaminases, and kidney function. Patients should be evaluated for risk factors for atherosclerosis with fasting blood glucose and lipid profile. Thyroid function tests, liver function tests, and bilirubin levels are determined, and appropriate biopsies performed [91].

Chest radiographs will detect cardiomegaly, active pulmonary infiltrates, and serositis. Work up for cardiopulmonary complications entails doing pulmonary function testing with lung diffusion testing, two-dimensional echocardiography, and high-resolution computed tomography (CT) scans [124]. Magnetic resonance (MR) imaging of the brain may be useful for evaluation of neuropsychiatric lupus, or of joints in cases of avascular necrosis. MR or CT angiography will assess for thrombi for lupus-related thrombosis.

Cognitive function testing particularly for memory and intelligence should be considered in cSLE, either if behavioral changes occur, or school performance declines. The Weschler Abbreviated Scale of Intelligence and Delis-Kaplan Executive Function System can be used for this purpose [79]. Dual-energy x-ray absorptiometry is used to evaluate bone mineral density in the background of long-term glucocorticoid use [151].

Prognostic Factors

Predictive laboratory factors for long-term kidney outcomes at early stages have been studied. These investigations are pertinent to define clinically relevant short-term and long-term targets of therapeutic intervention [116]. Early decrease in 24-h proteinuria (<0.8 g/day) is the best predictor of long-term kidney outcome in patients with SLE. Another study reported that decreased proteinuria at 12-months follow-up was the best predictor of kidney outcome at 7 years for an ethnically distinct group of patients with severe lupus nephritis [159]. Notably, these studies also showed that the addition of other variables, such as level of serum creatinine and hematuria, did not improve the predictive value of 24-hours proteinuria [159].

Models have been developed that predict long-term outcomes in lupus nephritis using patient response data following therapy. Both proteinuria and serum creatinine levels at 1 year were important components for these models; urinalysis was not shown to add value [96]. In cSLE, low level of complement C3 in conjunction with high serum creatinine is associated with progressive kidney failure. A recent review on disease severity and progression, including data from 26 studies showed that high levels of creatinine (>1.5 mg/dL) at disease onset was a predictor for progression to kidney failure [97].

Prospective analysis of prognostic factors shows that anti-dsDNA antibodies did not predict a flare. High titers of antibodies specific for dsDNA using *Crithidia* immunofluorescence can predict with modest accuracy the presence of lupus nephritis (sensitivity 57%, specificity 97%) [77].

There are promising combinations of urinary and serum non-invasive biomarkers to predict long-term outcome and to estimate the degree of irreversible and chronic kidney damage in patients with lupus nephritis [167]. Urinary levels of both neutrophil gelatinase-associated lipocalin (NGAL) and monocyte chemo-attractant protein-1 (MCP-1) are predictive of renal outcomes [163]. Another prospective study, which evaluated ten urinary biomarkers in pediatric patients with lupus nephritis, showed that decline of GFR was associated with persistent high levels of TGFβ, transferrin, and LFABP, indicating continued renal inflammation [25].

Management

Trials in adults have informed guidelines for treatment of lupus nephritis in children and adolescents [43, 51, 78, 103]. Treatment is geared to promote remission, limit disease exacerbations/flares, and prevent kidney failure. Response definitions vary between studies, but cSLE definitions have been proposed (Table 6). Management of lupus nephritis is based on disease severity and risk of progressive kidney damage.

Lupus nephritis class I and II are associated with good prognosis. Conservative treatment (see below) is recommended. Although no additional immunosuppressive therapy is needed for the nephritis, patients require continued monitoring. The development of worsening proteinuria or elevated creatinine may indicate conversion to other nephritis classes. Class III, IV, V, and mixed (III/IV + V) class lupus nephritis requires therapy with systemic immunosuppression in addition to high-dose corticosteroids. Aggressive therapy is necessary when children present with nephrotic syndrome, or for findings on kidney biopsy of active cellular proliferation and necrosis involving ≥40% of glomeruli. Two treatment phases are utilized: (i) Induction, which lasts on average 3 to 6 months; and (ii) Maintenance where immunosuppressive treatment is reduced over time [56, 129]. Lupus nephritis class IV is the most severe form of nephritis and requires aggressive therapy. The long-term effect of

Table 6 Definitions of kidney outcomes in patients with cSLE and lupus nephritis [103]

Outcome measure	Definition
Core renal parameters	Proteinuria (spot protein to creatinine ratio)
	Kidney function (creatinine clearance, serum creatinine)
	Urine sediment (leukocytes, red cells, or casts)
Renal response definitions	
Substantial response (complete remission)	Inactive urine sediment (<5 leukocytes and < 5 red cells/hpf; no casts) Urine protein to creatinine ratio < 0.2 Normal kidney function (estimated GFR >90 mL/min/1.73 m^2)
Moderate response	>50% improvement in 2 of 3 core renal parameters (maximum protein to creatinine ≤ 1.0), without clinically relevant worsening of the remaining parameter
Mild response	30–50% improvement in 2 of 3 core renal parameters, without clinically relevant worsening of the remaining core parameter
No response	Patients who do not qualify for any improvement as above

GFR glomerular filtration rate, *hpf* high powered field remission after treatment depends upon response to therapy [81]. In 86 patients followed for 10 years, compared to nonresponders, those achieving complete remission had superior patient survival (95% vs. 60%) and renal survival (94% vs. 31%).

Initial Therapy for Proliferative Lupus Nephritis

Corticosteroids form the foundation of therapy. While first-line for rapid control of inflammation, time- and dose-dependent treatment-related toxicity exists. Maximum doses of oral corticosteroids of 2 mg/kg/day (60 mg/day) are advised. Pulse methylprednisolone is effective in treating severe, active disease and allows for rapid reduction of oral prednisone doses. An observational study examined the efficacy and safety of repeat pulse methylprednisolone on response rates and in prednisone sparing in lupus nephritis [134]. The optimal starting dose and oral regimen are not well established. For guidance on initial therapy, consensus plans have been developed. Corticosteroid strategies include primarily oral or primarily IV routes, and mixed IV and oral route [103].

The original 1980 NIH study laid the foundation for cyclophosphamide (oral or IV) use as first-line therapy for induction. Patients randomized to prednisone and intermittent IV cyclophosphamide (0.5 to 1 g/m^2 monthly for 6 doses) had superior renal survival, compared to azathioprine (AZA) plus prednisone, or prednisone alone. Lower cumulative exposures with IV compared with oral cyclophosphamide resulted in fewer cytopenias, less hemorrhagic cystitis, and better adherence [9]. Subsequent efforts to lower cyclophosphamide exposure and reduce side effects led to the Euro-Lupus nephritis trial. Ninety patients with proliferative lupus nephritis were randomized to receive either the NIH cyclophosphamide regimen or a low-dose IV regimen (500 mg every 2 weeks for 6-doses). Not only was no difference seen in kidney outcomes at 41 months or at 10 years, but also less toxicity and fewer severe infections occurred with the lower dose regimen [66]. Efficacy of IV cyclophosphamide (NIH protocol) was also seen in Polish [153] and US [84] children with lupus nephritis class III and IV followed for 32 and 36 months, respectively. Kidney biopsies completed before and after treatment showed decreased activity index without increased chronicity index. Significant improvement was observed in creatinine clearance, urine protein excretion, hypertension, and SLEDAI score, allowing for >50% reduction in corticosteroid dose.

Although the ACCESS trial of abatacept, a CTLA4-Ig construct/fusion protein that blocks the CD28/CD80 costimulatory pathway for T-cell activation, did not show additive benefit for initial treatment of lupus nephritis [1], the use of low-dose Euro-lupus protocol for cyclophosphamide has resulted in a major change in initial treatment guidelines [129, 168]. At 12 months, patients in the placebo arm who received IV cyclophosphamide (500 mg every 2 weeks) achieved a complete renal response rate of 46% (overall response rate 64%) [1]. Approximately 40% patients in the ACCESS trial were black and 40% were Hispanic: these patient populations had not been widely represented in the European trials [66]. However, children under 18 years were not represented.

Mycophenolate mofetil (MMF) is an effective initial agent for lupus nephritis in adults and children [41]. Multiple trials have demonstrated comparable efficacy of MMF to cyclophosphamide, including the landmark trial of 140 multiethnic patients treated with MMF (1 g to 3 g/day) or monthly IV cyclophosphamide (0.5 to 1 g/m^2). Not only was remission significantly more frequent in the MMF group after 6 months, but the safety profile was also more favorable. The Aspreva Lupus Management Study (ALMS) was a multiethnic international prospective study of 370 patients with proliferative lupus nephritis, comparing MMF (3 g/day) to cyclophosphamide for induction [5]. At 6 months, the response rate (complete and partial response) was 56% with the former and 53% with the latter. By 3.5 years, complete responses were seen in 62% of MMF and 59% of cyclophosphamide treated subjects. Both treatments had similar adverse events, with more gastrointestinal side effects with MMF.

Subgroup analysis, in black and Hispanic patients, demonstrated better response rates with MMF (60%) compared to cyclophosphamide (39%) [5]. While a meta-analysis showed similar renal response for cyclophosphamide and MMF in class IV nephritis [71], data on effectiveness in the severe forms of the illness is limited.

In cSLE with proliferative LN, a 51 patient UK cohort treated with corticosteroids and either MMF or cyclophosphamide showed equivalent reductions in proteinuria, serum creatinine and disease activity scores at 8 and 14-months follow-up [145]. Time to kidney flare was 343–451 days in cyclophosphamide and MMF groups. Parameters of disease activity (ESR, anti-dsDNA antibodies, C3) also improved in both groups. The recommended induction dose of MMF in children is 1200 mg/m^2/day, and may be adjusted according to tolerance, efficacy, and trough MPA blood levels.

Monoclonal antibodies targeting CD20 expressed on B cells have demonstrated clinical improvement of lupus nephritis in many observational studies. Significant improvements in disease activity, anemia, autoantibody titers, hypoalbuminemia, and proteinuria were reported in 63 children treated with 104 courses of rituximab during a 10-year period [164]. The Lupus Nephritis Assessment with Rituximab (LUNAR) study was a large, global, phase III, randomized, placebo-controlled trial comparing rituximab added to MMF and corticosteroids for induction therapy of proliferative lupus nephritis [128]. After 1 year, while there was no significant difference in complete or partial response (57% vs. 46% with placebo, $P = 0.18$); post-hoc analysis associated extent of peripheral B-cell depletion with complete remission. Among patients who achieved complete B-cell depletion, 47% achieved complete remission, compared with 13% of study participants with incomplete depletion [50]. The duration of B-cell depletion was also associated with better response. Nonsignificant trends were also reported in complete renal response rates at 3 and 12months in an Italian cohort of 54 patients with proliferative lupus nephritis (71% rituximab, 65% cyclophosphamide, 53% MMF) [109]. Studies on newer anti-CD20 agents, for example, ofatumumab and obinituzumab, also appear to be beneficial in patients who achieve complete B-cell depletion.

Belimumab is a monoclonal antibody that suppresses and inhibits the activity of B-cell activating factor (BAFF), also known as BLyS (B-lymphocyte stimulator). The soluble form of BAFF is overexpressed in active lupus nephritis. Belimumab was superior to placebo in 1684 non-renal adult onset patients with SLE, as add-on therapy (to MMF, cyclophosphamide, or azathioprine) [110]. A post-hoc analysis on 52-week outcomes revealed improved kidney outcomes: kidney flare rates, proteinuria, and kidney function. In the global lupus nephritis-BLISS phase III trial of 448 patients, belimumab improved 2-year response rates, with a number needed to treat of 9 [45]. Modification of induction protocols based on belimumab trials are likely to occur, as pediatric data is published.

Calcineurin inhibitors (cyclosporine, tacrolimus, voclosporin) have immunomodulatory and nonimmune-mediated roles in treatment. They inhibit T-cell proliferation as well as reduce proteinuria, through stabilization of podocyte cytoskeleton and afferent arteriole vasoconstriction [17, 104]. A randomized trial on 60 Asian patients with lupus nephritis class III, IV, and V reported similar 6-month complete response rates to therapy with steroids and either tacrolimus (75%), MMF (70%), or IV cyclophosphamide (60%) [89]. Serum albumin increased and proteinuria decreased faster in the tacrolimus cohort. A larger randomized controlled trial of 150 patients assigned to initial therapy with either tacrolimus or MMF reported 6-month complete response in 62% and 59%, respectively [106]. However, at median follow-up of 61 months, there was non-significant trend toward more nephritis flares with tacrolimus (54%) compared to MMF (38%). The incidence of a cumulative composite outcome (decline in creatinine clearance ≥30%; advanced CKD; death) was similar for both groups [106].

Calcineurin inhibitors have been studied in a multi-targeted approach to initial therapy for proliferative lupus nephritis. In a randomized controlled trial of 368 patients also treated with IV methylprednisolone and prednisone, the overall response was higher in patients receiving 24 weeks of MMF (1 g/day) plus tacrolimus (4 mg/day) than those receiving IV cyclophosphamide by the NIH protocol (84% vs. 63%) [92]. Voclosporin, an analog that does not require drug-level monitoring, has been studied in a phase 2 trial of induction therapy, in combination with MMF (2 g/day) and rapid steroid tapering. Among 265 geographically diverse patients at 6 months, the multi-target therapy achieved superior remission rates (27–33%) over placebo (19%) [130]. Higher complete renal remission rates persisted at 12 months, although increased rates of adverse events occurred with voclosporin. Initial results from the phase 3 AURORA trial of voclosporin are encouraging. A meta-analysis of 45 induction trials involving 4222 patients with proliferative disease, including children, showed higher remission rates with MMF, calcineurin inhibitors, and multi-target therapy than with IV cyclophosphamide [115]. Although longer-term outcomes are needed, calcineurin inhibitors are a satisfactory option for some patients with lupus nephritis.

Although no longer considered first line, azathioprine has been shown to be effective in select patients. In a Dutch study, 87 patients with proliferative LN responded similarly to oral steroids and either IV cyclophosphamide (750 mg/m^2; 13 pulses in 2 years) or azathioprine (2 mg/kg/day) combined with IV methylprednisolone [53]. However, after 5 years, relapses were higher in the latter group.

Initial Therapy for Membranous Nephropathy

Due to the favorable prognosis of adults with membranous LN with sub-nephrotic proteinuria, no additional immunosuppressive therapy is indicated and anti-proteinuric measures (section "Prognostic Factors") alone are recommended. However, pure membranous LN with nephrotic-range proteinuria is associated with thrombosis, doubling of serum creatinine in 20% and kidney failure in 25% of affected children [119]. In cSLE, consensus guidelines recommend corticosteroid and nonsteroidal immunosuppression in all patients.

In lupus nephritis class V, the first-line agent for immunosuppression is unclear. In 42 patients enrolled in a randomized trial of nephrotic-range proteinuria (age 13–60 years), remission rates at 1 year were superior with cyclosporine (83%), followed by cyclophosphamide (60%) and prednisone alone (27%) [10]. However, on long-term follow-up of 103 patients, kidney outcomes were nearly identical (95% complete response rate and 10-year renal survival of 86%) using corticosteroids with either oral cyclophosphamide, chlorambucil, azathioprine, cyclosporine, MMF, or methotrexate [108]. The Kidney Disease Improving Global Outcomes guideline recommends therapy with either MMF, cyclophosphamide, cyclosporine, or rituximab [78].

In an open-label trial of azathioprine and prednisone, complete remission occurred in 67% of 38 patients at 12 months, with an overall response (complete and partial remission) of 89% [105]. The cumulative 10-year incidence of kidney flares was 32%, and 16% had $\geq$30% decline in GFR. Better long-term renal survival was seen with steroids and cyclophosphamide, compared to steroids alone [9]. A randomized trial on 19 patients with 83 ± 59 months follow-up reported 91% response with corticosteroids plus chlorambucil alternating over 6 months, compared to 50% with corticosteroids alone [107].

A pooled analysis on two large randomized trials of MMF ($n = 33$) and IV cyclophosphamide ($n = 32$) reported no difference in proteinuria and serum creatinine at 24-weeks follow-up. Subgroup analysis of patients with nephrotic syndrome showed no difference in response rates [123]. Another study found that 6 of 10 patients treated with cyclosporine had reduction in proteinuria <1 g/day and two had reduction to 1–2 g/day at 43-months follow-up [122]. While half the patients had decrease in activity index on repeat biopsy, a rise in chronicity index was common. In another randomized trial on 28 patients with pure membranous nephropathy, better response at 6 months was reported with corticosteroids and tacrolimus, than with steroids and MMF (100% vs. 75%; $P = 0.09$) [106]. Relapses were common after cyclosporine was stopped. In 40 patients, multi-target induction therapy using corticosteroids plus MMF with tacrolimus achieved complete remission at 6 months in 50%, compared to 5% with IV cyclophosphamide [14]. There was no increase in adverse events in patients receiving multi-target therapy.

Maintenance Therapy

Following completion of induction therapy, maintenance therapy is required. Without it, flares are common and portend worsening kidney function, kidney failure, and even death [118]. Thus, the goals of maintenance therapy are to sustain remission while avoiding the toxicity of treatment regimens, and to prevent relapses and flares. Research supports use of MMF and azathioprine, but the duration of maintenance therapy is not evidence-based. Expert opinion suggests continuation for 2 to 3 years after complete remission of lupus nephritis is established. Repeat kidney biopsy showing histologic remission during maintenance may help in the decision-making to taper off therapy.

MMF has emerged as the therapy of choice for maintenance, although AZA is an alternative particularly in pregnant patients. A prospective comparison of three drugs following cyclophosphamide-induced remission of class III or IV lupus nephritis was performed in 54 patients [34]. Patients were randomized to quarterly pulse cyclophosphamide (0.5–1 g/m^2), azathioprine (1–3 mg/kg/day), or MMF (500–3000 mg/day). Event-free survival for the composite endpoints (death and kidney failure) at 72 months was significantly higher with MMF and AZA than IV cyclophosphamide. Five deaths (four in cyclophosphamide group; one in MMF group) and five kidney failure events (three with cyclophosphamide; one each with MMF and azathioprine) developed during follow-up. Relapse rate was significantly lower in MMF compared to the cyclophosphamide group, as were the adverse events [34].

In the European MAINTAIN proliferative lupus nephritis trial, 105 patients managed by Euro-lupus cyclophosphamide induction were assigned to MMF (2 g/day) or azathioprine (2 mg/kg/day) [65]. At 48-months follow-up, nephritis flares were similar (19–25%) with MMF or azathioprine, as were activity and chronicity indices on repeat biopsy. The multiethnic ALMS maintenance trial compared azathioprine (2 mg/kg) and MMF (2 g/day) in 227 patients, following induction therapy with either MMF or IV cyclophosphamide. Composite outcomes including death, kidney failure, doubling of serum creatinine, flares, or need for rescue therapy were two-fold lower with MMF (16% vs. 32%) [42]. Serious adverse events were similar between the two groups.

Calcineurin inhibitors have been proposed as maintenance therapy. Compared to azathioprine, cyclosporin was non-inferior based on rate of flares, preservation of kidney function, and reduction in proteinuria. In 70 patients who achieved remission with induction therapy, tacrolimus and azathioprine achieved similar rates of relapse [32]. A study on 16 patients showed comparable reduction of proteinuria, and similar blood levels of albumin and creatinine following therapy with tacrolimus and MMF at 106 weeks [171]. Similarly, a Japanese study on 26 patients treated with tacrolimus (3 mg/day) maintenance therapy and followed for 5 years demonstrated reduced lupus activity and stable GFR [76].

The optimal dose and duration of corticosteroid therapy during the maintenance phase is not clear. In a placebo-controlled randomized trial that examined the feasibility of such withdrawal, prednisolone was discontinued in seven patients and continued at low dose in eight. Over the next 36 months, renal flare occurred in one patient in former group, compared to four in the latter (three renal flare; one major extrarenal flare) [46].

Conservative Management

Non-immunosuppressive therapy is imperative to reduce the risk of kidney failure. Renin-angiotensin-aldosterone blockade is used for its anti-proteinuric and antihypertensive effects, including in adult-onset disease [73]. The blood pressure should be controlled below the 90th percentile for age, sex, and height. Lipid levels should be monitored. Routine use of statins had no clinically significant reduction in carotid intima-media thickening [139]. Nephrotoxic drugs should be avoided. Bone protection should follow non-pharmacologic and pharmacologic measures, particularly with prolonged corticosteroid use.

Adjuvant therapy with hydroxychloroquine (HCQ) or chloroquine reduces the risk of flares of lupus nephritis, kidney failure, and death. A systematic review showed strong evidence supporting their use in preventing flares and promoting patient survival [133]. In a longitudinal cohort of 459 patients administered HCQ or chloroquine for ~5 year, patients showed significantly reduced disease activity, decreased orbidity, and reduced cumulative corticosteroid dose [114]. Additional benefits include improved lipid and glucose metabolism, reduced risk of thromboembolism and cardiovascular events, and fewer infections and malignancies [133]. Although HCQ is well tolerated, there is small risk of maculopathy and loss of visual acuity. Risk factors for maculopathy include HCQ dose >5 mg/kg/day, duration of use >5 years, impaired kidney or liver function, and underlying macular disease. The mean maintenance dose of HCQ in adults is 200 or 400 mg/day. Appropriate ophthalmologic screening is advised at start of therapy, and then annually or biannually depending on risk factors.

Refractory Lupus Nephritis

KDIGO defines complete and partial remission to assess response to treatment. Complete remission is return of kidney function to baseline, and decline in urine protein/creatinine to <5 mg/mg. Partial remission requires stable or improved kidney function, and ≥ 50% reduction in urine protein/creatinine ratio [78]. Treatment-resistant or refractory disease is identified by failure to improve within 3–4 months, absence of partial remission after 6–12 months, or failure of complete remission after 2 years. Within that framework, patients who fail to respond to initial treatment with MMF or cyclophosphamide may be switched to the alternate therapy. Of 85 patients with refractory or relapsing nephritis after cyclophosphamide as initial therapy, 87% responded to MMF within a median time of 3 months [126]. In 17 MMF-resistant patients, adding tacrolimus resulted in significant reduction in proteinuria and 70% response rates at 2 years [36]. In 21 patients with refractory disease, multitargeted therapy using MMF, cyclosporine, and corticosteroids achieved response in 70% patients within 1 year [75]. Open label investigations also support a role for rituximab [165]. Of 22 patients with refractory class III or IV nephritis, add-on therapy with rituximab (0.5 to 1 g on days 1 and 15) was associated with satisfactory response in 12 [162]. In a meta-analysis of 223 patients treated with rituximab for refractory illness, 51% had complete and 27% had partial remission [3].

Intravenous immunoglobulins (IVIg) have been studied in lupus nephritis and for nonrenal features of SLE. Evidence from few trials and observational studies suggests that IVIg lowers levels of dsDNA antibodies, with reduction in proteinuria and improvement in kidney function [113]. While therapy with IVIg and subcutaneous immunoglobulin [21] are effective in some patients with refractory lupus nephritis, most trials were uncontrolled. Due to limited availability of IVIg, its use tends to be reserved for patients with hypogammaglobulinemia, resulting either from active lupus or from the effect of medications.

Plasmapheresis has been reported to be successful in anecdotal cases, and is believed to remove circulating immune complexes. Plasmapheresis added to oral cyclophosphamide and prednisone was compared to therapy without plasmapheresis in severe lupus nephritis [88]. At mean follow-up of 136 weeks, there was no difference between the groups in terms of renal and patient survival. Although not justified for routine use, plasmapheresis may be helpful in patients with refractory antiphospholipid antibodies and contraindications to anticoagulation, or those with both positive lupus and ANCA serology.

Relapses of Lupus Nephritis

Of patients who achieve complete or partial remission, kidney relapses occur in 27–66%

[49]. Relapse of nephritis is a predictor for development of kidney failure. Relapses arise due to medication non-adherence, but may occur with altered maintenance immunosuppression. The diagnosis is based on clinical criteria and includes worsening lupus serology (decrease in C3 and C4, increase in anti-dsDNA antibodies), increasing proteinuria, active urine sediment, and increase in serum creatinine from baseline [103]. Active lupus serology and/or urine sediment requires close monitoring as they are associated with relapse of nephritis. Proteinuric relapses are managed with increased maintenance immunosuppression or steroid dose. Repeat kidney biopsy aids in identification of class switch from non-proliferative to proliferative LN in the presence of worsening urinary findings. This histologic conversion can be found in 40–76% of cases following relapse [51]. Treatment is tailored based on kidney biopsy findings. Active lesions with a nephritic relapse require a change in immunosuppression, using an agent with different mechanism of action, intensified therapy, and/or increased dose of steroids. A less aggressive approach is indicated in patients with pure membranous LN.

Extrarenal Disease

The management of SLE is challenging due to chronic relapsing and remitting course, wide spectrum of features from mild to life-threatening conditions, and multisystem involvement with varying severity. The goals of treatment are thus to: (i) maintain low degree of lupus activity using immunosuppressive agents, and avoid known triggers, (ii) prevent organ damage, (iii) reduce comorbidities secondary to lupus and its treatment, and (iv) address fatigue and pain, which often are not associated with active lupus.

Glucocorticoids remain the standard therapy for nonrenal SLE, the dose and duration being dependent on the severity of manifestations. HCQ is recommended due to beneficial effects on arthritis and cutaneous lesions, reduced risk of disease flares, and better cardiac outcomes [133]. Immunosuppressive agents are indicated for persistent disease activity, and as steroid-sparing agents to maximize control of disease activity while minimizing drug-related-morbidity. There is lack of randomized controlled trials that compare the efficacy and safety of different immunosuppressive agents in cSLE. For mild to moderate SLE, methotrexate, azathioprine, and MMF are commonly used, while cyclophosphamide and rituximab are indicated for life-threatening disease [43]. IVIg and rituximab have shown benefit in therapy of severe thrombocytopenia with inadequate response to high dose glucocorticoids [95].

Geographic, Race, and Ethnic Considerations

Different ancestries and ethnicities display different disease characteristics, disease activity/damage scores, and outcomes in cSLE populations around the world [48, 61, 86, 87]. Poverty, low educational status, lack of health insurance, and poor social support, which are more prevalent in non-white populations, have negative impact on disease course and outcomes [29]. Therefore, cSLE management should consider the impact of racial/ethnic background, as well as costs and availability for immunosuppressive and biological agent use.

Two cohorts of Amerindian ancestral cSLE and adults SLE patients, GLADEL (Latin American Group for the Study of Lupus) and LUMINA (Lupus in Minorities: Nature vs Nurture), showed poor outcomes compared to patients of Caucasian ancestry, possibly related to genetic background and socioeconomic factors [158]. Recently, the first Latin American clinical practice guidelines for the treatment of SLE: GLADEL and Pan-American League of Associations of Rheumatology (PANLAR) was published. Pharmacologic options were examined for pediatric and adult lupus nephritis, as well as musculoskeletal, mucocutaneous, cardiac, pulmonary, neuropsychiatric, and hematological involvements and the antiphospholipid syndrome. While more African American and Hispanic patients responded to MMF than cyclophosphamide in adult SLE, there is reduced availability of MMF and tacrolimus in many Latin American countries, making cyclophosphamide the best option for induction. For pediatric lupus nephritis, the panel of pediatric rheumatologists also suggested IV cyclophosphamide for induction, despite the risk of ovarian and testicular toxicities, and azathioprine for maintenance treatment.

Geographical considerations for lupus nephritis have been also reported by Asian populations. Relatively low frequency of disease flares was observed in Chinese patients receiving maintenance with low-dose prednisolone and MMF [170]. Calcineurin inhibitors are also treatment options for pediatric LN. In real-world practice, initial data on tacrolimus treatment came chiefly from Asian children. Therapy with tacrolimus seems promising for maintaining and re-inducing remission in Japanese cSLE patients [155].

Outcomes

Activity and Damage

The challenge of disease activity and need for estimating damage has led to development of different disease tools [142]. These instruments are reliable and valid for use in cSLE, each with similar psychometric properties. The overall disease activity scores assessed in practice are the British Isles Lupus Assessment Group (BILAG), the Systemic Lupus Erythematosus Disease Activity Index (SLEDAI), and the Physician's Global Assessment of Disease Activity (MD Global). There is consensus that all patients be regularly evaluated for disease activity, using either SLEDAI 2000 (SLEDAI-2K) or pediatric BILAG 2004 [52]. Due to simplicity, feasibility, and good metrologic properties, MD Global should also be included for disease activity in clinical practice and research [54].

Disease activity should be measured at disease diagnosis and during disease course. Data from the Childhood Arthritis and Rheumatology Research Alliance (CARRA) showed delays in diagnosis of 3 to 12 months in 23% and severe delay of >1 year in 9% of 598 cSLE patients. No significant differences were observed in SLEDAI among children and adolescents with rapid compared with moderate or severe delay of cSLE diagnosis [131]. The Brazilian cSLE Registry evaluated three different groups with distinct time intervals between onset of signs/symptoms and disease diagnosis in 1555 cSLE patients: short time interval to diagnosis (<1 month, 4%), intermediate time interval (≥1 and < 3 months, 33%), and long time interval (≥3 months, 63%). The median SLEDAI-2 K was significantly higher in patients with short time interval to diagnosis compared to the other groups, indicating more active and multisystem presentation [112].

The course of illness in cSLE is characterized by episodes of disease activity requiring intensive drug therapy, followed by periods of improvement. An international consensus defines cSLE flares as "measurable worsening of disease activity in at least one organ system, involving new or worse signs of disease that may be accompanied by new or worse SLE symptoms; depending on the severity of the flare, more intensive therapy may be required" [23]. Consensus criteria for global flares in cSLE define thresholds for minor, moderate, and major flares. These criteria include the most relevant disease activity parameters, and are important for gauging systemic responses to interventions intended to treat systemic or organ-specific manifestations of cSLE [26]. An intervention that is effective in reducing proteinuria in cSLE patients with lupus nephritis would not be desired if at the same time it evoked new onset mucocutaneous or neuropsychiatric lupus.

An equally important outcome measure is the SLICC/ACR damage index (SDI) score. The SDI describes cumulative damage and likely reflects disease activity and severity over time. High scores indicate more severe organ damage. The commonly scored items scored are proteinuria, scarring, alopecia, and cognitive impairment [64]. High-impact manifestations are weighted: myocardial infarction, stroke, avascular necrosis, malignancy, significant tissue loss, gastrointestinal infarction or resection, and dialysis dependence [142]. SDI score is predominantly disease-related, although side effects of high dose glucocorticoids and immunosuppressive drugs also contribute [142]. European recommendations suggest yearly evaluation using SDI score [52].

The SDI has been validated in cSLE [142]. Accrual damage may have long-lasting physical and psychosocial issues for cSLE patients. A pediatric version of SDI is available, with two pediatric-specific domains: growth failure and delay in development of secondary sexual characteristics (observed in 15% and 11% of patients, respectively) [55]. In cSLE, cohorts followed 2–4 years, the frequency of any damage (SDI >1) ranges from 28% to 52% [64]. Afro-Caribbean ancestry and major organ and system involvements (lupus nephritis class III/V, cerebrovascular accidents, vasculitis, alveolar hemorrhage, or myocarditis) were associated with greater damage. A study of 111 cSLE patients showed median time to stroke, kidney transplant, replacement arthroplasties, and myocardial infarction at 20, 24, 34, and 39 years, respectively [51].

Consequences of cSLE therapy or disease activity may contribute to specific damage in children and adolescents, especially infections, gonadal dysfunction/infertility, and osteoporosis [142]. Infections are an important cause of morbidity, and increase cumulative damage, as reported with invasive fungal infections (candidiasis, aspergillosis, cryptococcosis, histoplasmosis, and paracoccidioidomycosis). Risk factors of infection include disease activity and duration, lymphopenia, leukopenia, neutropenia, hypocomplementemia, functional asplenia, and therapy with immunosuppressive agents [142]. Primary immunodeficiency (C2, C4, C1q, C1r-s, IgG2, IgM, and IgA deficiencies) was identified in 22% of cSLE patients and contributes to risk of systemic infections. SDI scores were higher in patients with primary immunodeficiency, compared to those without these conditions [70].

The term infertility is generally inadequate for adolescents with cSLE, since infertility is defined as inability to have a child after 1 year of sexual activities without the use of contraception [142]. Therefore, the nomenclature gonadal (ovarian or testicular) dysfunction is appropriate for adolescent and youth SLE populations. Global evaluation of ovarian reserve comprises new markers of ovarian function: anti-Müllerian hormone levels and ovarian ultrasound to assess antral follicle count. Two studies assessed these parameters in adolescents and young female cSLE patients. Decreased ovarian reserve markers, in spite of presence of regular menstrual cycles, were observed in cSLE patients after intravenous cyclophosphamide use [2]. Another study evaluated ovarian reserve parameters and anti-corpus luteum antibodies in adult SLE patients with pediatric onset, and showed that a high cumulative methotrexate dose was a possible cause of subclinical ovarian dysfunction for this population [40].

Overall testicular function was systematically assessed in 30 adolescents and adults with SLE and 30 healthy subjects. Low sperm count, low motile sperm, low normal sperm forms, reduced testicular volumes, and elevated follicle stimulating hormone levels occurred significantly in SLE patients compared to healthy controls, with similar frequencies of anti-sperm antibodies. The chief contributing factor for these testicular abnormalities was the intravenous cyclophosphamide use. The duration of time from the last dose of this alkylating therapy was 5.1 ± 3.7 years, indicating persistent or long-lasting damage to primordial sperm cells, and sperm abnormalities [147].

cSLE patients may also have a significant impact on bone health and a permanent reduced bone accrual over years, resulting in a reduction of bone mass peak and a high risk of osteoporosis in early adulthood [142]. Low aerobic fitness, muscle weakness, chronic inflammation, glucocorticoid use, pubertal delay, and reduced intake of calcium and vitamin D may be responsible for reduced bone mineral density in cSLE patients [117].

SLE on Dialysis

The mortality rate on dialysis (22% at 5 years) is similar to that reported for other causes of pediatric-onset kidney failure [62]. Patients with SLE have similar outcomes on chronic dialysis with either hemodialysis or peritoneal dialysis [31]. Due to concerns for peritonitis, some centers prefer hemodialysis for patients on high dose immunosuppression [74]. Peritoneal dialysis may be preferable in patients with antiphospholipid antibody syndrome due to the possibility of hemodialysis access failure from thrombosis [141].

The 10-year survival rate for SLE patients with CKD5 is better for those taking prednisone and hydroxychloroquine than corticosteroids alone, and outcome of dialysis is worst for patients on no immunosuppressive medication [22]. Whereas azathioprine and cyclophosphamide are cleared with hemodialysis, the dialytic clearance (▶ Chap. 86, "Drug Dosing in Abnormal Kidney Function in Children") of other immunosuppressive drugs is minimal [98]. Cyclophosphamide dose is usually reduced 50% and given one day before the next hemodialysis session [8]. As opposed to patients in the ICU with oliguric AKI who receive IV cyclophosphamide, there is no need for intravenous fluids or bladder irrigation for anuric patients with kidney failure. There is no data on clearance of immunosuppressive agents during peritoneal dialysis.

Patients should continue to be followed by their rheumatologist after declaration of kidney failure, as extrarenal flares are common. SLE patients on dialysis who continued to have two or more follow-up visits annually with rheumatologists had improved longevity and were more likely to receive effective immunosuppressive therapy [22].

SLE Following Transplantation

One-third of cSLE patients with lupus nephritis and kidney failure receive a kidney transplant within 5 years. Based on data from the US Renal Data System (USRDS) from 1995 to 2006, 51% were African American and 24% Hispanic [62]. There were significantly fewer kidney transplants amongst adolescents (as opposed to younger children), black and Hispanic children, and those with Medicaid (compared to private insurance). Mortality from SLE with CKD5 is almost double among blacks compared to whites [62].

Serological markers of disease activity (complement C3 and C4; dsDNA antibodies) are even less accurate measures of disease activity during the post-transplantation period. While glomerular immune complex deposition is seen on half of surveillance biopsies, recurrent lupus nephritis is very low: less than 3% of patients had symptomatic disease [35]. Overall, graft survival and infection-related complications are comparable between transplant patients with lupus nephritis-associated kidney failure and with other causes (▶ Chap. 84, "Renal Transplantation: Non-infectious Complications and Long-Term Outcome") [35, 62]. Only 7% of graft failures are attributable to recurrent disease (Renal Transplantation: Disease Recurrence). However, patients with recurrent nephritis have a fourfold increased risk for graft failure [35].

A history of APLS is associated with reduced 10-year graft survival. To a lesser degree, the presence of antiphospholipid antibodies in SLE patients is also a risk for early graft failure. Anticoagulation with warfarin or low molecular weight heparin is usually provided to reduce the risk of graft thrombosis, but does not improve graft survival [161]. For most pediatric patients with SLE, the overall survival post-transplant is comparable to that of children who receive a kidney transplant for other causes [16].
